Decoration of Ti/TiO$_2$ Nanotubes with Pt Nanoparticles for Enhanced UV-Vis Light Absorption in Photoelectrocatalytic Process

Lucio C. Almeida* and Maria V. B. Zanoni

Departamento de Química, Instituto de Química, Universidade Estadual Paulista Júlio Mesquita Filho (UNESP), Rua Francisco Degni, 55, Bairro Quitandinha, 14800-900 Araraquara-SP, Brazil

Nanotubes of TiO$_2$ (TiO$_2$NTs) were decorated with nanoparticles of Pt via cathodic deposition. These nanoparticles were uniformly distributed, highly separated and spaced all over TiO$_2$NT surface to shorten deposition times with Pt particle sizes proportional to the applied charges. The Pt/TiO$_2$NT photoelectrode shows an intense absorption peak in the visible region with a significant red shift induced by Pt deposition on TiO$_2$NT surface, decreasing the band gap energy from 3.21 eV to 2.87 eV. Pt/TiO$_2$NT photoelectrode was tested as photoanode in the photoelectrocatalytic oxidation of Acid Red 29 dye with great success. Total decolorization and 92% of total organic carbon removal were obtained after 120 min of treatment by using Pt/TiO$_2$NT photoelectrode which was superior to the values obtained for the undecorated one (87% and 68%, respectively) due to better use of irradiation and minimization of charge recombination.

Keywords: photoelectrocatalytic process, Pt decorated TiO$_2$, dye degradation

Introduction

The exponential increase of industrial activities and the high demand for manufactured products have caused a considerable impact on the environment. In this context, new environmentally friendly techniques to eliminate or at least reduce the effect of recalcitrant pollutants have been developed. Among the different techniques employed for contaminant removal, electrochemical advanced oxidation processes (EAOPs) have aroused great interest for degradation/mineralization of organic pollutants due to their potential environmental compatibility, since it rears no generation of secondary pollution. Moreover, the EAOPs are being widely studied because of the strongly oxidant hydroxyl radical (•OH) generation which reacts non-selectively with organic compounds in waters.

Among the different EAOPs, photoelectrocatalysis by using semiconductor materials has been extensively investigated in recent decades, with emphasis on the semiconductor TiO$_2$. The combination of bias potential and UV irradiation has contributed to many applications, such as wastewater treatment. Although many studies reported in literature have demonstrated the efficiency of TiO$_2$ as photoanode for degradation/oxidation of persistent organic compounds, the interest of improving the properties of this material with focus on decreasing the high band gap value (3.20 eV) for TiO$_2$ in anatase phase which limits its photoactivity at low wavelengths, has gained attention.
The doping or band gap engineering of TiO$_2$ has been made in order to shift the absorption spectra to longer wavelengths. This is obtained by the incorporation of metal ions into the lattice, such as Pt,$^{18,19}$ non-metals such as C and N,$^{20,21}$ and composites of semiconductors such as WO$_3$/TiO$_2$.\textsuperscript{22}

Platinum decorated TiO$_2$ nanotubes (Pt/TiO$_2$NTs) have been destined for methanol, glucose and dopamine oxidation.\textsuperscript{23-26} The introduction of Pt nanoparticles on TiO$_2$NTs (undecorated) has improved its electrical conductivity, catalytic activity and its stability in several chemicals.\textsuperscript{27-29} Furthermore, the properties of this metal may also favor the enhancement of organic compound degradation (i.e., enhancement of the photocatalytic efficiency), since the Fermi levels of these metals are lower than the TiO$_2$NT conduction band when deposited on this material, allowing the electrons to move towards the noble metal Fermi levels, reducing the electron-hole recombination rate.\textsuperscript{30-32} The decrease in electron density within the TiO$_2$NTs causes the holes which freely diffuse to the surface where oxidation of organic compounds can occur.

Park \textit{et al.}\textsuperscript{33} deposited Pt nanoparticles on the TiO$_2$NT structure by photoreduction method and their physicochemical properties were investigated. In this work, Pt decorated photoelectrode exhibited higher photocatalytic performance than the undecorated one on the photodegradation of Methylene Blue dye. Pt/TiO$_2$NT photoelectrodes prepared by platinum deposition-precipitation method were also studied by Zhu \textit{et al.}\textsuperscript{34} and their photocatalytic performance was evaluated by the degradation rates of Methyl Orange solution under UV-vis light irradiation. Using stable TiO$_2$NTs, An \textit{et al.}\textsuperscript{35} studied the Pt nanoparticle deposition on nanotubular TiO$_2$ surface via photodeposition process and the photocatalytic performance was also evaluated by the photodegradation of Methylene Orange under UV light irradiation. According to these authors, Pt/TiO$_2$NTs exhibited higher photocatalytic activity than the undecorated one. Hosseini and Momeni\textsuperscript{36} recently evaluated the performance of Pt/TiO$_2$NT electrodes for electrochemical oxidation of formic acid. Nevertheless, the literature does not explore the increase of electrical conductivity of Pt/TiO$_2$NTs to evaluate its performance in the photoelectrocatalytic oxidation of an organic pollutant.

In this context, the present work reports the preparation of Pt/TiO$_2$NT photoelectrodes by galvanostatic electrodeposition of Pt nanoparticles on TiO$_2$NT surface. The influence of Pt introduction onto TiO$_2$NT surface was evaluated by systematic characterization of the morphology and photoactivity response when irradiated by UV-Vis light. In order to assess the photoelectrocatalytic (PEC) performance of the Pt/TiO$_2$NT photoelectrode, this material was applied to the degradation of the azo dye Acid Red 29 (AR29) (see formula in Figure 1). This textile dye was chosen as model compound due to its wide applicability and because 70% of the dyes usually consumed in the world are based on azo dyes, characterized by the presence of one or more azo groups (–N=N–).\textsuperscript{3,37} Percentages of color removal and changes of total organic carbon (TOC) of AR29 dye solutions were monitored as responses. Decay kinetics for AR29 dye was followed by high-performance liquid chromatography (HPLC) during the dye mineralization. All results are compared with TiO$_2$NTs without modification.

![Figure 1. Molecular formula for acid red 29 (AR29) azo dye. Color index number: 16570.](image)
acid (≥ 99.9% purity, Sigma Aldrich) of ethanolic solution and at room temperature. In this electrochemical method, deposition times of 15, 20, 30 and 40 min were studied and a potentiostat/galvanostat (AUTOLAB Model PGSTAT 302) controlled by GPES software was used during the electro deposition experiments.

Characterization of the Pt/TiO$_2$NT photoelectrodes

TiO$_2$NT (undecorated) and Pt/TiO$_2$NT photoelectrodes were characterized according to their physical structure by means of X-ray diffraction (XRD) on a Siemens D 5000 using radiation in the 4 to 70$^\circ$ range. The structures and morphologies were characterized by field emission gun scanning electron microscopy (FEG-SEM), Zeiss Supra 35, coupled to an energy dispersive X-ray (EDX). The photochemical properties were analyzed by diffuse reflectance spectroscopy (DRS), by using an UV/Vis/NIR spectrophotometer (PerkinElmer Lambda 1050) equipped with a 150 mm Integrating Sphere and a high sensitivity Gridless-PMT detector operating between 200 and 800 nm. The UV/Vis/NIR spectrophotometer was calibrated with a Spectralon standard (Labsphere USRS-99-020).

Photocurrent measurements of both photoelectrodes were performed with a Potentiostat/Galvanostat Model 263 (EG&G Princeton Applied Research Co., USA), by using a conventional three-electrode cell with a double jacket where external thermostated water recirculated to maintain the solution temperature at 25°C. A Philips high-pressure Hg lamp (I = 9.2 W m$^{-2}$ and 125 W) without glass protection (inserted in a quartz cylinder) was immersed in 250 mL of 0.100 mol L$^{-1}$ aqueous sodium sulfate (Na$_2$SO$_4$). A platinum wire and an Ag/AgCl (KCl, 3.0 mol L$^{-1}$) were employed as counter and reference electrodes, respectively. The linear sweeps were carried out using a scan rate of 10 mV s$^{-1}$, in the range potential of −0.5 to 2.0 V under and without lamp exposure, separated from the photoanode by a distance of 2.0 cm.

Evaluation of the photoelectrocatalytic activities of TiO$_2$NT and Pt/TiO$_2$NT photoelectrodes

Photoelectrocatalytic experiments were performed by using a conventional three-electrode electrochemical cell with cylindrical cell of 500 mL capacity with a double jacket, where the temperature was maintained at 25°C via external water recirculation by using a thermostat.

TiO$_2$NT (undecorated) and Pt/TiO$_2$NT photoelectrodes were used as anodes, platinum gauze as a cathode (auxiliary electrode) and Ag/AgCl (KCl, 3.0 mol L$^{-1}$) as the reference electrode. The geometric areas of the photoanodes were 5.0 cm$^2$, whereas the platinum gauze cathode was 4.0 cm$^2$. For all PEC experiments, photoanode and platinum gauze cathode were arranged around a high-pressure mercury lamp (125 W) without the bulb. The gap between photoanodes and Hg lamp was ca. 2.0 cm. The PEC assay experiments were performed with a TECTROL R3/AS1 power supply and under potentiostatic mode. The cell potentials were monitored with a MINIPA ET-2042D digital multimeter connected in parallel to the electrochemical cell.

Comparative PEC treatments (by using TiO$_2$NT and Pt/TiO$_2$NT photoelectrodes) of 500 mL of 85.4 mg L$^{-1}$ AR29 solution (35 mg L$^{-1}$ TOC) in 0.05 mol L$^{-1}$ Na$_2$SO$_4$ were conducted at potential of 2.0 V vs. Ag/AgCl (KCl, 3.0 mol L$^{-1}$) in the range of pH from 3.0 to 6.0 and under continuous stirring with a magnetic bar to provide the transport of species towards the electrodes. Samples were withdrawn from the cell at regular time intervals. The color removal of AR29 solutions was monitored from the absorbance decay at the wavelength of 508 nm (corresponding to maximum absorption) using a Hewlett Packard 8453 UV-Vis spectrophotometer operating in the range of 190-900 nm and the efficiency of dye decolorization was calculated as:

\[
\text{Decolorization } \% = \left[ \left( A_i - A_t \right) / A_i \right] \times 100
\]

Decolorization $\% = \left[ \left( A_i - A_t \right) / A_i \right] \times 100$ (1)

where $A_i$ and $A_t$ are the maximum absorbance ($\lambda = 508$ nm) before and after irradiation, respectively.

The degradation of AR29 solutions was monitored from the abatement of their TOC, determined on a Shimadzu TOC-V CPN analyzer and reproducible TOC values with an accuracy of ± 2% were always found by injecting 800 µL samples to the TOC analyzer. Decay kinetics of AR 29 were followed by reversed-phase HPLC using a Shimadzu 10 Avp LC fitted with a Spherisorb ODS2 (5 µm, 150 mm x 4.6 mm i.d.) column and coupled with photodiode array detectors at $\lambda = 508$ nm. The mobile phase used in isocratic mode was 75:25 (v/v) acetonitrile/phosphate buffer (pH = 3.5) with a flow rate of 0.6 mL min$^{-1}$ at 25°C.

Results and Discussion

Characterization of TiO$_2$NT and Pt/TiO$_2$NT photoelectrodes

Figures 2a-2e illustrate the morphologies of TiO$_2$NT photoelectrodes produced via anodization of Ti sheets before (Figure 2a) and after (Figures 2b-e) modification with Pt nanoparticles by electrodeposition methodology using different deposition times. The results indicate that the adopted methodology promoted the formation/growth of highly ordered and structured nanotubes, with
mean inner diameters varying from 104 to 124 nm and with thickness of about 13 nm (see Figures 2a and 2b). The synthesized TiO$_2$NTs were remarkably well-aligned (vertically to the Ti substrate) with nanotube layers of up to 1.20 µm length, as shown in the inset of Figure 2a.

The Pt/TiO$_2$NT photoelectrodes prepared by electrochemical Pt deposition employing a cathodic current density of 10 mA cm$^{-2}$ during 15, 20, 30 and 40 min (Figures 2b, c, d and e, respectively) show that the time of electrochemical reduction of chloroplatinic acid affects directly the Pt nanoparticles formation. By using 15 min of cathodic deposition the TiO$_2$NT surface is decorated with uniformly distributed Pt nanoparticles with diameter of 2-5 nm (Figure 2b), which were confirmed as Pt atoms by EDX measurements. The cross-sectional view illustrated at the inset of Figure 2b shows that the Pt nanoparticles were also uniformly deposited on TiO$_2$NT walls without any sign of aggregation, with nanoparticle sizes similar to those described above (2-5 nm). Figure 2c shows that Pt/TiO$_2$NT photoelectrode prepared employing 20 min of electrolysis presents deposits with bigger and more irregularly distributed Pt nanoparticles, with Pt deposits reaching up to 30 nm. Figures 2d and 2e (for 30 and 40 min of Pt deposition, respectively) indicated that the Pt deposits are deeply irregular with cluster formation, which compromises the deposits’ quality. Furthermore, Pt/TiO$_2$NT electrodes obtained for 40 min of electrolysis showed Pt nanoparticles with varying sizes and poorly distributed Pt
clusters, when compared with the electrodes produced in shorter times (see Figure 2e). Therefore, we can verify that Pt particles sizes were proportional to the applied charge for electrodeposition, i.e., more aggregation of Pt nanoparticles was observed at longer deposition times. The results indicate that Pt deposition by electrochemical reduction on TiO$_2$NTs is very efficient for obtaining Pt nanoparticles regularly distributed on TiO$_2$NT surface, i.e., highly separated and spaced over all electrode surface, and short deposit times, such as 15 min can promote small particle formation and more efficient coating. Although EDX analysis has been used for all TiO$_2$NT photoelectrodes to confirm the formation and presence of platinum, for simplicity only EDX spectrum of Pt/TiO$_2$NT photoelectrode obtained during 15 min electrolysis is depicted, as can be seen in Figure 2f.

Figure 3 compares the X-ray diffraction patterns of the TiO$_2$NT and the Pt/TiO$_2$NT photoelectrodes (deposits of 15 min). As can be seen, the shape of X-ray diffraction peaks of Pt/TiO$_2$NT photoelectrode was similar to the undecorated one, due to the small Pt concentration in relation to the TiO$_2$NTs and to the detection limit of the equipment employed. All the diffraction peaks identified and located at 25.5, 38.1, 48.1, 54.8 and 62.7° are indexed as anatase TiO$_2$ (JCPDS card No. 21-1272) corresponding to reflections of (1 0 1), (0 0 4), (2 0 0), (1 0 5) and (2 0 4) planes, respectively.\textsuperscript{35}

Photocurrent-potential curves in dark conditions (curve a) and under UV-Vis illumination by using TiO$_2$NT and Pt/TiO$_2$NT (Pt electrodeposition times of 15, 20, 30 and 40 min) photoelectrodes in 0.100 mol L$^{-1}$ Na$_2$SO$_4$ are compared in Figure 4. All photocurrents generated for Pt/TiO$_2$NT (decorated) photoelectrodes (curves b-e, Figure 4) are higher than the undecorated one (Figure 4, Curve f), and gradually reaches current plateaus (saturated states) at positive potentials near 1.0 V under UV-Vis lamp exposure, with insignificant current response in the dark in the potential range of −0.5 to 2.0 V. Taking into consideration that the irradiation source includes UV and visible light content, it seems that the Pt introduction could be improving the light absorption in relation to TiO$_2$NTs (undecorated) that is activated only at wavelengths lower than 380 nm.

Nevertheless, comparing the effect of Pt nanoparticle size deposit on TiO$_2$NT surface it is possible to observe that the photocurrents generated were inversely proportional to the electrodeposition time. The maximum photocurrent densities for Pt/TiO$_2$NT is obtained for Pt electrodeposition times of 15 min, approximately 41% higher than obtained for electrodeposition carried out on 40 min. The respective values of photocurrent (taken at 1.5 V) for all Pt/TiO$_2$NT (decorated in different times) photoelectrodes are shown in Table 1. This behavior can be simply explained by the formation of smaller and more uniformly distributed Pt nanoparticles which serve as efficient electron traps (i.e., Schottky barriers) to avoid the electro-hole recombination.\textsuperscript{40}

On the other hand, superfluous Pt content and/or a large particle size distribution on the TiO$_2$NT surfaces would block the transferring of electrons to the Pt nanoparticles to some extent, increasing the electron-hole recombination.\textsuperscript{41}

In short, the modification of TiO$_2$ with Pt smaller nanoparticles promotes efficient light absorption and reduction on the recombination of the photogenerated electron-hole pairs generated under UV-Vis light. These photogenerated holes can be trapped in the photoanode surface by H$_2$O/OH$^-$ species, giving rise to ‘OH radicals, which could improve the mineralization of organic compounds in favorable conditions.\textsuperscript{5}
The other effect observed for photocurrent-potential curves by using TiO$_2$NT and Pt/TiO$_2$NT (Pt electrodeposition times of 15, 20, 30 and 40 min) photoelectrodes in 0.100 mol L$^{-1}$ Na$_2$SO$_4$ (Figure 4) is the shift on flat-band potentials ($E_{fb}$). This corresponds to the situation in which there is no charge accumulation at semiconductors and that at n-type semiconductors photoanodic currents only flow at potentials more positive than $E_{fb}$. The flat-band potentials for TiO$_2$NT (undecorated) and for all Pt/TiO$_2$NT photoelectrodes were calculated using the Butler equation, and their values are exhibited in Table 1. From similar plots, the introduction of Pt nanoparticles promotes a shift of 167 mV in the flat-band potentials to less positive potential when TiO$_2$NTs are decorated with smaller Pt nanoparticles (electrochemical deposition during 15 min). This could be indicative of a better band bending and of a consequent improvement in the charge separation.

These results are confirmed by comparing the UV-Vis diffuse reflectance spectra of TiO$_2$NTs (undecorated) and Pt/TiO$_2$NTs (electrodeposits of 15 min), as shown in Figure 5. The spectra indicates a strong light absorption in the UV region, ascribed to the charge transfer from the valence band (2p orbital of TiO$_2$NTs) to the conduction band (3d orbital of the Ti$^{4+}$) for both photoelectrodes. But, marked peaks around 650 nm (absorption in the visible region) were observed for Pt/TiO$_2$NT materials. The increase in the absorption peak intensity in the visible region is observed a significant red shift induced by platinum deposited on TiO$_2$NTs probably due to the formation of an intra-gap energy level inside the band gap of TiO$_2$NTs. Figure 6 shows the estimated band gap values (obtained by extrapolating the linear region to ($\alpha h\nu$)$^{1/2} = 0$) for TiO$_2$NT and Pt/TiO$_2$NT photoelectrodes, calculated with the Kubelka-Munk function (equation 2): 

$$\alpha (h\nu) = A(h\nu - E_g)^n$$

where $\alpha$ is the extinction coefficient, $h$ is Planck’s constant (J s), $\nu$ is the incident light frequency (s$^{-1}$), $A$ is the absorption constant, $E_g$ is the band gap (eV) and $n$ is the absorption coefficient. An $n$ value of 1 was chosen for all the samples, indicating a direct allowed optical transition. The band gap of TiO$_2$NT (undecorated) and Pt/TiO$_2$NT photoelectrodes were estimated to be 3.21 and 2.87 eV, respectively (Figure 6). Thus, the results indicate that Pt deposition on TiO$_2$NT photoelectrode results in an increase in the visible-light response, i.e., that the deposition of Pt nanoparticles effectively extends the absorption from UV to a visible region by the reduction of the band gap value. Taking into account that the irradiation system adopted as source promotes irradiation in UV and visible light, an improvement in the photodegradation of pollutants is expected when TiO$_2$NTs are decorated with Pt nanoparticles. Further studies were carried out comparing the degradation of AR29 dye by using both electrodes.

![Figure 6](image_url) Plots of ($\alpha h\nu$)$^{1/2}$ vs. $h\nu$ employed to calculate the band gap values. Kubelka-Munk function $\alpha(h\nu) = A(h\nu - E_g)^n$ for (a) TiO$_2$NT (undecorated) and (b) Pt/TiO$_2$NT (decorated by electrochemical deposition during 15 min) photoelectrodes.
Degradation of AR29 dye at TiO$_2$NT and Pt/TiO$_2$NT photoelectrodes

In order to test the photoelectrocatalytic activities of TiO$_2$NT (undecorated) and Pt/TiO$_2$NT (decorated with Pt by electrochemical method during 15 min) photoelectrodes, PEC assays were conducted for 85.4 mg L$^{-1}$ AR29 solutions (35 mg L$^{-1}$ TOC) in 0.05 mol L$^{-1}$ Na$_2$SO$_4$ (pH 6.0) at bias potential of 2.0 V vs. Ag/AgCl by using UV-Vis irradiation. Figure 7 compares the percentage of color removal and the TOC abatement obtained using TiO$_2$NT (undecorated) and Pt/TiO$_2$NT photoelectrodes. The percentage of decolorization was obtained by monitoring the absorbance at $\lambda = 508$ nm, where azo group is acting as chromophore.$^3$

As can be seen at Figure 7, PEC assays conducted by using Pt/TiO$_2$NT photoelectrode were more efficient than the undecorated one for both responses, i.e., for efficiency of decolorization and TOC abatement.

![Figure 7](image-url)

Figure 7. Percentage of color removal and TOC abatement vs. degradation time of 500 mL of a 85.4 mg L$^{-1}$ Acid Red (AR29) solution in 0.05 mol L$^{-1}$ Na$_2$SO$_4$ by the PEC process and applying 2.0 V vs. Ag/AgCl for: (□) TiO$_2$NT (undecorated) and (■) Pt/TiO$_2$NT (for 15 minutes of Pt electrochemical deposition) photoelectrodes. Applied pH: 6.0.

Then, the effect of pH was studied by monitoring the dye decolorization in 0.05 mol L$^{-1}$ Na$_2$SO$_4$ at pH 3.0, 4.5 and 6.0, and bias potential of 2.0 V vs. Ag/AgCl by using UV-Vis irradiation. For all degradation experiments, slight pH decreases with prolonging electrolysis time up to 120 min were observed. This drop of pH can be related to the formation of aliphatic carboxylic acids as found for treatment of other dyes.$^{3,50}$ Taking into account that at acidic conditions there is no need of pH correction, all the experiments were done in acidic medium. The percentages of color removal calculated from equation 1 and for three pH values are plotted in Figure 8 for both photoelectrodes. Total color removal of the AR29 solutions was obtained by using the Pt/TiO$_2$NT (decorated) photoelectrode at pH values of 3.0 and 4.5 after 60 min of electrolysis. On the other hand, at pH 6.0 partial color removal (87%) was obtained for the same time of electrolysis. A similar tendency was observed while using TiO$_2$NT (undecorated) photoelectrodes, with maximum decolorization efficiencies at pH values of 3.0 and 4.5. However, decolorization efficiencies obtained by using the undecorated material were slightly lower compared to the decorated one for 60 min of electrolysis.

![Figure 8](image-url)

Figure 8. Effect of pH on color removal vs. degradation time of 500 mL of a 85.4 mg L$^{-1}$ Acid Red (AR29) solution in 0.05 mol L$^{-1}$ Na$_2$SO$_4$ by the PEC process and applying 2.0 V vs. Ag/AgCl for: (□, △, ○) TiO$_2$NT (undecorated) and (■, ▲, ●) Pt/TiO$_2$NT (for 15 minutes of Pt electrochemical deposition) photoelectrodes. Applied pH: (□, △) 3.0, (▲, ●) 4.5 and (○, ○) 6.0.

The adsorption process of ionic form of the AR29 dye (AR29$^-$) onto Pt/TiO$_2$NT and TiO$_2$NT surfaces is probably the first step in the process of AR29 oxidation.$^{51}$ So, the effect of pH on photoelectrocatalytic oxidation of AR29 may be securely explained by the relation/interaction between the surface charge of TiO$_2$ surface and the acid dissociation constant (pK$_a$ = −3.08 at 25 °C) of AR29. Charge on TiO$_2$NT surface is formed by either protonation (Ti–OH + H$^+$ → Ti–OH$_2^+$) or deprotonation (Ti–OH + OH$^-$ → Ti–O$^–$ + H$_2$O) of the Ti–OH bonds.$^{52}$ It is known from literature that the isoelectric point (IEP) for TiO$_2$ varies between 5.2 and 5.5.$^{53}$ The IEP (or point of zero charge, PZC) is the pH at which the surface charge is electrically neutral. On the other hand, the surface is positively charged at a pH < IEP and negatively charged at pH > IEP.$^{54}$ The anionic form of the AR29 (AR29$^-$) predominates above its pK$_a$ value. Therefore, the pH range from −3.08 to 5.5 (i.e., at pH between the pK$_a$ and the IEP) which may be the optimum condition for the adsorption of AR29$^-$ onto Pt/TiO$_2$NT and TiO$_2$NT surfaces, explains why the kinetics of the AR29 oxidation was favored at more acid conditions. For pH values above 5.5 the TiO$_2$NT surface is negatively charged and the adsorption process of AR29$^-$ is not favored.

Better results shown by the Pt/TiO$_2$NT photoelectrode compared with the undecorated one can be explained by
the fact that when coupling metallic Pt with TiO₂NTs, photogenerated electrons can flow from the semiconductor to the metallic Pt forming the Schottky barrier on the metal-semiconductor interface³¹,³³,³⁵,³⁶,³⁸ due to the higher energy of conduction band of the TiO₂NTs (undecorated) compared with the new formed Fermi level of Pt/TiO₂NTs. So the electrons on the Pt surface can be transferred to adsorbed O₂ to form O₂⁻·, while holes accumulated at the valence band of TiO₂NTs led to the additional production of the strong and non-selective radical ‘OH. Finally, the hydroxyl radical formed reacts with the AR29 dye until their total mineralization, i.e., conversion into carbon dioxide, water and inorganic ions. In other words, Pt nanoparticles deposited on the TiO₂NT surface act as electron scavengers, promoting a better separation of electron-hole pairs. Consequently, more ‘OH radicals were generated, enhancing the photocatalytic activity of TiO₂NTs and the decolorization and degradation rates. Moreover, Pt/TiO₂NT photoelectrodes have shown a stronger light absorption both in UV and visible regions than that of undecorated ones (see Figure 8), which coincides with the absorption lines in the regions (i.e., at λ = 254, 373, 410, 441, 542 and 572 nm) obtained for the employed Hg lamp. Therefore, more photons with specific wavelength can be absorbed, thus enhancing the photoelectrocatalytic activity. Furthermore, AR29 solutions were exposed directly to the same high-pressure Hg lamp during 30 min and significant changes in the absorbance (at λₘₐₓ = 508 nm) were not observed, indicating that this dye is not directly photolyzed.

The mineralization of AR29 solutions by PEC process was monitored as a function of the TOC abatement. Figure 9 shows the TOC-time plots obtained for the degradation of the 85.4 mg L⁻¹ AR29 solution by using TiO₂NT (undecorated) and Pt/TiO₂NT photoelectrodes at pH values of 3.0, 4.5 and 6.0. It can be observed that TOC decayed more rapidly for the Pt/TiO₂NT photoelectrode when compared to the undecorated one, after 120 min of degradation. At this time, TOC reductions of 92%, 89% and 80% were obtained for pH values of 3.0, 4.5 and 6.0, respectively. On the other hand, at the same time and by using the TiO₂NT (undecorated) photoelectrode only 66%, 67% and 61% of TOC abatement (after 120 min electrolysis) were found for pH values of 3.0, 4.5 and 6.0, respectively. These results corroborate the findings of photocatalytic and decolorization obtained in this work (Figures 4 and 8, respectively), due to the better adsorption of ionic form of the AR29 dye (AR29⁻) onto Pt/TiO₂NT and TiO₂NT surfaces at more acid conditions (as explained above). As expected, higher efficiency on the dye mineralization was obtained by using the Pt/TiO₂NT material probably due to the better separation of electron-hole pairs generating additional ‘OH radicals, which accelerate the oxidation process, as it has been explained above. Furthermore, the TOC content in AR29 solutions did not vary when exposed to Hg lamp source during 120 min, confirming that the direct photolysis of this dye can be neglected. Although the decorated photoelectrode has yielded 92% TOC removal of dye solution, the formation of recalcitrant products (i.e., products hardly destroyed by photogenerated ‘OH radicals) may have prevented their total mineralization."
(t_d) of 8.35 min. Direct photolysis of the AR29 dye was discarded because its content in solution remained constant after 120 min under UV lamp exposure and without potential application by the photoelectrochemical cell.

Figure 10 highlights the quick and almost total degradation of the 85.4 mg L\(^{-1}\) AR29 solution in 0.05 mol L\(^{-1}\) Na\(_2\)SO\(_4\) at pH 3.0 by using Pt/TiO\(_2\)NTs (decorated) applying 2.0 V vs. Ag/AgCl and under UV-Vis irradiation exposure during 30 min. Similar concentration decay was observed using the TiO\(_2\)NT (undecorated) photoelectrode under the same experimental conditions. As can be seen in the inset in Figure 10, the concentration decays fitted well with equation expected for pseudo first-order kinetics. From this analysis, pseudo first-order constants (k\(_1\)) of 3.0 \(\times\) 10\(^{-3}\) s\(^{-1}\) \((R^2 = 0.996)\) and 1.36 \(\times\) 10\(^{-3}\) s\(^{-1}\) \((R^2 = 0.987)\) were obtained for Pt/TiO\(_2\)NT (decorated) and TiO\(_2\)NT photoelectrodes, respectively. The fastest AR29 dye degradation promoted by the Pt/TiO\(_2\)NT photoelectrode can be ascribed to Pt nanoparticles deposited on the TiO\(_2\)NT surface, which act as electron sinks promoting a better separation of electron-hole pairs, generating more 'OH radicals, and consequently also promoting a better light absorption than TiO\(_2\)NT (undecorated) photoelectrode.

These results are in agreement with the TOC abatement illustrated in Figure 9, indicating that the use of Pt/TiO\(_2\)NT photoelectrodes in the photoelectrocatalytic oxidation of dye are not only more efficient in decolorization of dye solutions, but also for TOC mineralization when compared to the undecorated one.

**Conclusions**

In this work, Pt decorated TiO\(_2\)NT photoelectrodes were prepared using different deposition times under galvanostatic condition. Platinum nanoparticles were more uniformly distributed, highly separated and spaced over the entire TiO\(_2\)NT surface in shorter deposition times. Additionally, it has been verified that Pt particle sizes were proportional to the applied charge, i.e., more aggregation (clusters) of Pt particles were observed at longer deposition times. Similarly, the higher photocurrent response was obtained by applying the Pt/TiO\(_2\)NT photoelectrode which presented a better Pt nanoparticle distribution on TiO\(_2\)NT surface. The band gap of this Pt/TiO\(_2\)NT photoelectrode was red shifted to the visible region in comparison with the undecorated one, and their band gap were estimated (by using Kubelka-Munk function) to be 3.21 and 2.87 eV, respectively.

The decolorization and mineralization rate of AR29 dye solutions were studied employing TiO\(_2\)NT (undecorated) and Pt/TiO\(_2\)NT photoelectrodes and at different pH values (3.0, 4.5 and 6.0). Although the total color removal of AR29 dye solutions has been achieved by using the Pt/TiO\(_2\)NT photoelectrode at pH values of 3.0 and 4.5 (i.e., pH values which are between the pK\(_a\) of AR29 and the IEP for TiO\(_2\)) after 60 min of electrolysis, at pH 6.0, only partial color removal (87%) was achieved at the same time. Similar tendency was observed for the undecorated photoelectrode, even if less efficient than the decorated one. Furthermore, TOC reductions of 66 and 92% were obtained at pH 3.0 (the optimum pH value) and after 120 min electrolysis by using TiO\(_2\)NT and Pt/TiO\(_2\)NT photoelectrodes, respectively. For both materials, the AR29 decay followed pseudo first-order kinetics with similar constant rates, which is double than with the Pt/TiO\(_2\)NTs electrode. This difference on TOC reductions showed that platinum nanoparticles improves the light absorption composed of UV and visible irradiation in relation to TiO\(_2\)NTs (undecorated) that is activated only by UV irradiation and, in addition, it can accelerate the dye mineralization due to the better separation of electron-hole pairs, generating additional ‘OH radicals, i.e., due to the higher photocatalytic activity of the Pt/TiO\(_2\)NT photoelectrode compared to the undecorated one. Finally, our results revealed that platinum modification of TiO\(_2\)NTs by using a simple method is a promising and an attractive way to develop photoelectrodes with high photocatalytic activity and capacity for dye oxidation improving the light absorption in a situation close to solar radiation.
