We compared the effect of three different exercise programs on patients with chronic obstructive pulmonary disease including strength training at 50–80% of one-repetition maximum (1-RM) (ST; N = 11), low-intensity general training (LGT; N = 13), or combined training groups (CT; N = 11). Body composition, muscle strength, treadmill endurance test (TEnd), 6-min walk test (6MWT), Saint George’s Respiratory Questionnaire (SGRQ), and baseline dyspnea (BDI) were assessed prior to and after the training programs (12 weeks). The training modalities showed similar improvements (P > 0.05) in SGRQ-total (ST = 13 ± 14%; CT = 12 ± 14%; LGT = 11 ± 10%), BDI (ST = 1.8 ± 4; CT = 1.8 ± 3; LGT = 1 ± 2), 6MWT (ST = 43 ± 51 m; CT = 48 ± 50 m; LGT = 31 ± 75 m), and TEnd (ST = 11 ± 20 min; CT = 11 ± 11 min; LGT = 7 ± 5 min). In the ST and CT groups, an additional improvement in 1-RM values was shown (P < 0.05) compared to the LGT group (ST = 10 ± 6 to 57 ± 36 kg; CT = 6 ± 2 to 38 ± 16 kg; LGT = 1 ± 2 to 16 ± 12 kg). The addition of strength training to our current training program increased muscle strength; however, it produced no additional improvement in walking endurance, dyspnea or quality of life. A simple combined training program provides benefits without increasing the duration of the training sessions.

Introduction

Skeletal muscle dysfunction is one of the most serious extrapulmonary manifestations of chronic obstructive pulmonary disease (COPD). This dysfunction limits exercise tolerance and is associated with complaints of fatigue and dyspnea even after minimal exertion (1). Deconditioning is almost certainly a contributing factor, given that patients with COPD have symptom-limited exercise tolerance, which compromises their cardiac fitness and further limits their exercise tolerance, leading to exacerbation of their symptoms after exertion (1).

Exercise programs aiming to restore muscle function could result in outcomes that are more favorable than those achieved with simple conditioning programs. The efficacy of pulmonary rehabilitation in COPD patients has been well established (2). Endurance training of the lower extremities, resulting in greater exercise tolerance, is an important component of these programs (3). However, the effect of endurance training on muscle weakness and wasting is less consistent (1). In addition, it is often difficult for COPD patients to perform high-intensity exercises due to dyspnea or hypoxemia (4). It has been reported that the increase in muscle strength obtained after strength train-
Patients and Methods

Patients and design

Fifty-one consecutive patients admitted to the Rehabilitation Center of Paulista State University (UNESP), School of Medicine at Botucatu, SP, Brazil, were invited to participate in the study. Patients were included in the study if they met the global initiative for chronic obstructive lung disease criteria for a diagnosis of COPD (12). Patients considered clinically unstable (i.e., who presented changes in medication dose or frequency, disease exacerbation, or hospital admissions in the preceding 8 weeks) were excluded. The occurrence of exacerbation was evaluated by self-reporting during clinic visits and was confirmed by reviewing the medical record. The following factors were also considered grounds for exclusion: chronic diseases such as malignant disorders, cardiovascular disease, insulin-dependent diabetes mellitus, osteoarthritis, use of oral corticosteroids, treatment non-compliance, and inability to perform the lung function test.

In groups of 3, patients were randomly assigned to one of the training modalities (ST, LGT, or CT). Each program consisted of three 1-h sessions per week over a period of 12 weeks.

Four patients did not complete the baseline evaluation and were excluded from the study. Therefore, the final sample was composed of 47 patients. Upon the arrival of each subject, the purpose and procedures involved in the study were explained and written informed consent was obtained. All procedures were approved by the Research Ethics Committee of the UNESP School of Medicine at Botucatu.

Pulmonary function and arterial blood gas analysis

Spirometry was performed before and after 15 min of inhalation of 400 mg salbutamol (Med-Graph 1070; Medical Graphics Corporation, USA). Forced expiratory volume in the first second is reported as liters, as percent forced vital capacity and as percent of reference values (13). Blood was drawn from the brachial artery with the patients at rest and breathing room air. Arterial oxygen tension and carbon dioxide tension (PaO₂ and PaCO₂) were determined with a blood analyzer (Stat Profile 5 Plus; Nova Biomedical, USA).

Nutritional assessment

Body weight and height were measured, and body mass index (BMI = weight/height²) was calculated. Body composition was evaluated using bioelectrical impedance (BIA 101A; RJL systems, USA). Resistance was measured on the right side of the body in the supine position. Fat-free mass (FFM, kg) was calculated using a group-specific regression equation developed by Kyle et al. (14). The FFM index (FFMI = FFM/height²) was also calculated. Lean body mass depletion was defined as an FFMI <15 kg/m² for women and <16 kg/m² for men (15).

Health-related quality of life and dyspnea

The Brazilian versions of the Saint George’s Respiratory Questionnaire (SGRQ) and of the Airways Questionnaire 20 (AQ20) were used to evaluate patient health-related quality of life (16,17) and the results are reported as percent (16,17). A similarly modified version of the baseline dyspnea index (BDI) (18), developed by Mahler et al. (19) was used to evaluate baseline dyspnea. Clinically significant improvement was defined as a decrease of ≥4% in the total SGRQ score (20).
Respiratory pressures, handgrip and peripheral muscle strength

We measured maximal inspiratory pressure by the method of Black and Hyatt (21). Forearm muscle strength was measured on the basis of handgrip strength of the dominant hand measured with a dynamometer (TEC-60; Technical Products, USA).

Peripheral muscle strength was assessed by the determination of the one-repetition maximum (1-RM). The agreed convention for 1-RM is the heaviest weight that can be lifted throughout the complete range of motion related to the exercise performed. The 1-RM was assessed for exercises carried out on weight training equipment (22): leg press (quadriceps, gluteus, hamstrings, and calf muscles), leg extension (quadriceps), lat pull-down (latissimus dorsi, trapezius, and biceps), bench press (pectoralis major and triceps), seated rowing (latissimus dorsi, trapezius and triceps), triceps pulley (triceps), and biceps curl (biceps). A warm-up of 3–5 min followed by 10 repetitions with a light load was performed prior to the test in order to minimize the effects of learning. The 1-RM test was initiated at a weight near the suspected maximum to minimize repetition fatigue. All participants attained the 1-RM within 3–5 attempts. Two to 3 min of rest were allowed between repetitions. The Valsalva maneuver was avoided, and the proper exercise performance technique for each muscle group was emphasized.

Exercise tolerance

A maximal exercise tolerance test was performed. The test consisted of symptom-limited graded exercise on a treadmill with patient breathing room air and its objective was to determine possible cardiovascular contraindications of exercise programs using a modified Bruce protocol (23). A constant workload treadmill test, used to assess endurance capacity, was performed on a separate day, subsequent to that on which the incremental exercise test was performed. After 3 min of warm-up, the treadmill was set at 80% of the maximum inclination and at the speed achieved during the baseline maximal incremental exercise test. Patients were instructed to walk at 80% of their maximum power output (i.e., exercise intensity probably above the lactate threshold) for as long as they could.

A 6-min walk test (6MWT) was also conducted after a

</table>
few minutes of practice, with the patients being instructed to walk on an oval 33.12-m course, attempting to cover the greatest distance possible in 6 min. A research assistant timed the walk, and standardized verbal encouragement was given to each patient. Peripheral oxygen saturation (SpO₂) was monitored throughout the test using a pulse oximeter (Ohmeda Biox 3700; Ohmeda, USA). Patients who presented hypoxia at baseline, as well as those whose SpO₂ decreased to <85% during the test, were given oxygen by a physical therapist, who wheeled an oxygen tank in a handcart alongside the patient. Before and after the test, the following data were obtained: SpO₂, heart rate, respiratory rate, dyspnea (Borg), and blood pressure. The distance covered was measured in meters. The minimal clinically significant improvement was also recorded (≥54 m) (24).

Exercise training programs

The ST consisted of seven exercises performed on weight training machines. Patients were submitted to three sets of 12 repetitions with a 2-min rest between sets and with a workload at 50-80% of that achieved on the 1-RM test. The 1-RM test was repeated every 3 weeks to re-establish the workload.

As can be seen in Table 1, the LGT consisted of 30 min of walking at a self-determined intensity and an additional 30-min of low-intensity resistance training with free weights, on exercise mats and on parallel bars. The LGT performed in our study corresponds to three metabolic equivalents of energy expenditure and can be classified as a low-intensity exercise program according to the American College of Sports Medicine recommendations for older adults (25,26). The number of repetitions used in the LTG was based on physiologic endurance principles, including a high number of repetitions with a low load (26). The CT consisted of 30 min of ST with only two series of 8 repetitions with a workload at 50-80% of 1-RM. The remaining 30 min were devoted to LGT at half the volume (i.e., 15 min of walking at a self-determined intensity and an additional 15 min at half the number of repetitions of low-intensity resistance training with free weights, on exercise mats and on parallel bars). All exercise regimens were conducted in 60-min sessions, which included pacing for breathing.

Statistical analysis

Data were analyzed statistically using the SigmaStat (version 2.03) statistical software (SPSS, Inc., USA). The sample size, calculated taking into consideration minimal clinically important differences in health-related quality of life (SGRQ total score ≥4%), was N = 10 for each training group. The following tests were carried out: Kolmogorov-Smirnov to assess the normality of variable distribution; descriptive analysis of data with values reported as means ± SD; repeated two-way ANOVA for comparisons between pre- and post-training values, taking into consideration the comparison among groups and the effect of training; one-way ANOVA for comparison of groups at baseline, and chi-square and Goodman tests to compare proportions. A covariance model of repeated measures analysis on independent groups was performed for the adjustment by sex of variables with gender influence (exercise tolerance and muscle strength). Percent changes (Δ) of all variables were calculated and the Pearson or Spearman coefficient of correlation was used to assess correlation between Δ values. Values of P < 0.05 were considered significant.

Results

Of the 47 patients initially evaluated, 13 (4 in the ST group, 6 in the LGT group, and 3 in the CT group) failed to complete the 12 weeks of the conditioning program due to one of the following reasons: disease exacerbation (N = 4), socioeconomic difficulty (N = 1), lack of motivation (N = 6), job conflict (N = 1), and nonspecific skeletal muscle complaints (N = 1). However, comparisons of these patients with those completing the programs did not show significant differences at baseline. Thirty-five patients concluded the training protocols with adequate adherence (ST = 11; CT = 11; LGT = 13), having completed more than 85% of the scheduled sessions.

General characteristics of the study population

Baseline characteristics of the remaining 35 patients are presented in Table 2. No differences were found between groups in terms of age, gender, body composition, airflow obstruction, or arterial blood gases. On average, the patients presented a moderate airflow obstruction. No patient presented evidence of arterial hypoxemia, defined as PaO₂ <55 mmHg/SpO₂ <89%. Three patients (1 in the CT group and 2 in the LGT group) presented a BMI <21 kg/m². Another three (one in the ST group and two in the LGT group) presented an FFMI <15 kg/m² (women) or <16 kg/m² (men). One LGT patient presented a low BMI and a low FFMI. At the end of the training period, none of the groups presented significant changes in lung function or body composition.

Effects of exercise training on health-related quality of life and dyspnea

No differences were observed in pre- or post-intervention scores for health-related quality of life and dyspnea in any training modalities studied (Table 3). Patients in the ST
group presented a significant post-training improvement in the SGRQ symptoms domain, activities domain and total scores, as well as in the AQ20 total score. Those in the CT group presented a significant post-training improvement in the SGRQ activities domain, impact domain, total scores, and in the AQ20 total score. Those in the LGT group presented a significant post-training improvement in the SGRQ symptoms domain and total scores. In addition, minimal clinically significant improvement in the total SGRQ score was found for 7 patients in the ST group (63.6%), 9 patients in the CT group (72.7%), and 9 patients in the LGT group (69.2%; P > 0.05). Although significant improvement in BDI was found only in the ST group, there was a minor, though consistent, trend towards improvement in BDI score in the CT and LGT groups.

Effects of exercise training on functional exercise tolerance

Results related to functional exercise tolerance are shown in Table 4. It can be observed that there was a significant increase in the 6-min walked distance and in the endurance time in the CT and ST groups. A minimal clinically significant improvement in the 6MWT was observed in 6 patients in the ST group (54.5%) and in 4 patients in the CT group (36.4%). In addition, we observed a tendency to a significant increase in 6MWT values and in the treadmill endurance time in the LGT group. Four LGT patients (30.8%) presented minimal clinically significant improvements in the 6MWT results.

Effects of training on respiratory and peripheral muscle strength

Pre- and post-training values of respiratory and peripheral muscle strength are presented in Table 4. Baseline peripheral muscle strength did not differ significantly among groups. Patients in the ST and CT groups presented a significant post-training improvement in all 1-RM values, whereas no significant changes in 1-RM values were observed in the LGT group. With the exception of the leg press exercise, 1-RM values were comparable for the ST and CT groups at baseline and at the end of training. With the exception of bench press in the CT group, all 1-RM values were significantly higher at the end of the program in the ST and CT groups than in the LGT group. In the ST group, the change in the 6-min walk
distance presented significant positive correlations with changes in 1-RM in the lat pull down ($r = 0.64; P = 0.0452$), 1-RM in the bench press ($r = 0.62; P = 0.0395$), and 1-RM in the leg extension ($r = 0.60; P = 0.0467$).

**Discussion**

The aim of the present study was to compare the results of three different exercise programs regarding body composition, quality of life, dyspnea, peripheral muscle strength, and exercise tolerance of COPD patients. We found that the strength-training component produced additional improvements in peripheral muscle strength. However, this type of training did not promote any additional benefit in exercise tolerance, dyspnea or health-related quality of life.

In the present study, ST, alone or combined with LGT, was effective in increasing the strength of the muscle groups trained. Supporting this finding, there is strong evidence that ST alone or combined with endurance training can lead to a significant improvement in muscle strength in COPD patients (5,8,27,28). In contrast with previous studies that showed increased muscle strength and higher endurance in COPD after low-intensity resistance training, we did not find a significant increase in muscle strength in the LGT group (9,10). Studies using cycling and arm cranking as a training modality have shown significant increases in lower and upper limb muscle strength (5,23,24). On the other hand, Mador et al. (29) did not observe any change in peripheral muscle strength after endurance training. These discrepancies may be attributable to the differences in the modalities and the intensity of training employed.

No significant changes in BMI, FFM or FFMI were found in our study in any group evaluated. This finding is in agreement with previous reports of increases in total FFM only when the rehabilitation process included nutritional support or supplementation with specific agents, such as testosterone or creatine (30–32). Moreover, body impedance is not accurate enough to detect small changes in body mass composition (14).

The ST and CT modalities produced significant and similar changes in health-related quality of life in the present study. The magnitude of the improvements shown in the present study (SGRQ total change = 11 ± 10 to 13 ± 14%) has been reported by others in Brazilian patients (33). The dyspnea in the ST group improved significantly, whereas it did not change significantly in the CT or LGT groups. The between-group difference for the change in dyspnea, however, was not significant. In fact, a recent systematic review of randomized controlled trials comparing different exercise programs for COPD showed that ST produced greater improvements in the dyspnea domain and in the total score of the Chronic Respiratory Disease Questionnaire when compared to endurance training (8).

The 6-min walking distance and the endurance time were higher in the ST and CT groups, in agreement with other reports (5,28). In the present study, the mean increase in the 6-min distance walked was less than 54 m. However, for some of the patients, the absolute value was greater than 54 m (54.4% in the ST, 36.4% in the CT, and 30.8% in the LGT). Mador et al. (29) reported similar results in patients submitted to a combined exercise program (strength and aerobic exercises). Moreover, Spruit et al. (28) and Ortega et al. (5) also showed an improvement in endurance time in COPD patients after an exercise

**Table 4.** Pre- and post-training mean values of functional exercise tolerance, as well as respiratory and peripheral muscle strength for patients in the strength training (ST), combined training (CT), and low-intensity general training groups (LGT).

program. The continuous (oval) tracks and number of practice tests related to 6MWT in the present study might have influenced our results (34). Recently, the distance walked on a continuous circular track exceeded the distance walked on a straight track by 13 ± 17 m in patients with COPD (34). The coefficient of repeatability for 3-day sessions was 51 and 65 m for the straight and circular tracks, respectively. Thus, for an individual patient, performing the test in different layouts results in less variability in 6-min walk distance then performing the test on a different day. Regarding the execution of a practice walk test, the distance walked is only slightly greater in a second test according to ATS recommendations (35).

We found a tendency towards increased exercise tolerance in the LGT group. Clark et al. (9), comparing the results obtained for a group of patients following a low-intensity exercise program with those found for a control group, also observed a significant increase in endurance time in the trained group. Similar results were reported by Normandin et al. (10). The low intensity of the LGT program and the reduced number of patients performing this training modality in our study might explain the lack of a statistical effect. Nevertheless, all exercise training programs studied were able to produce significant and similar changes in health-related quality of life, in agreement with previous reports (5, 10, 27, 29).

In the literature, two different modalities of CT, shorter and longer sessions of endurance training combined with ST, have been compared to endurance training alone (5, 27, 29). The longer CT session protocols resulted in increased muscle strength but provided no greater improvement in exercise tolerance or health-related quality of life than did endurance training alone (27, 29). Interestingly, the shorter CT session protocols provided the best benefits for the patients and have been suggested to represent an optional strategy for patients with COPD (5). This is in agreement with our findings showing that a combination of training modalities is effective without increasing the duration of the sessions.

An interesting finding of the present study was the correlation between changes in muscle strength and in 6-min walk distance. We were able to find only one study (36) that showed a significant correlation between percent changes in leg muscle function and constant workload treadmill endurance test performance after strength training alone. However, the cited study did not assess trunk muscle strength (latissimus dorsi, trapezius, pectoralis major) as assessed in the present study. Some of these trunk muscles may take on an accessory respiratory function when the primary respiratory muscles are dysfunctional or cannot meet the ventilatory demand (37). Therefore, improvement of trunk muscle strength may benefit respiratory mechanics, resulting in better exercise capacity (38).

The present study has some methodological limitations. Although we used reliable tools to evaluate patient ability to carry out daily life activities, such as the 6MWT (39), we were unable to directly assess maximal oxygen uptake due to equipment limitations. Moreover, the reduced number of patients in the LGT group may have influenced the amount of benefits of this type of training. As previously mentioned, the sample size was calculated considering minimal clinically important differences in health-related quality of life (SGRQ total score improvement ≥4%), that indicated N = 10 in each training group. It is possible that the number of patients studied (ST = 11; CT = 11; LGT = 13) was not sufficient to observe differences related to other variables in the LGT group, probably due to a type II error. However, it is unlikely that including more patients in the study would have changed the conclusion that, except for the peripheral muscle strength, the improvements were similar for the three study groups. In a systematic review, O’Shea et al. (40) showed that strength training was found to have strong evidence for improving peripheral muscle strength; however, no strong evidence for strength training was found for outcome measures such as exercise capacity, dyspnea or health-related quality of life. Further investigations are required to evaluate the impact of strength training programs on activities of daily living, balance, upper-limb function, and self-care in patients with COPD.

The low-intensity training regarding LGT may also have influenced our results. However, the literature shows that this training type can result in significant benefits for patients with COPD (6, 9, 10). Rehabilitation programs are scarce and just a small number of patients have access to this treatment, mainly in Brazil, where resources are limited. The available structure allows training with mats, free weights, parallel bars, and free walking and this has been our rehabilitation strategy for many years. Therefore, the present study was designed to determine whether the addition of strength training performed on gym equipment can maximize the benefits of our current program. In addition, although the various CT programs have yielded significant benefits, our design did not allow us to assess patient motivation or preference for any of the training modalities. Four of the 6 patients who dropped out of the LGT stated a lack of motivation. Since the statistical analysis did not show significant differences among the groups, no conclusions can be drawn regarding the effects of different exercise modalities and session durations on COPD patient adherence to the training programs. Finally,
an unblinded assessment was necessary, similar to some previous studies (5,28,36).

The results of the present study support the view that the addition of a strength-training component to an endurance training program of COPD patients increases muscle strength. However, it cannot promote additional increases in exercise endurance, dyspnea, or health-related quality of life. Moreover, a relatively simple training program combining LGT and ST can produce significant improvements in muscle strength, in exercise tolerance and in health-related quality of life, even when the sessions are of standard duration. Finally, the benefits of physical conditioning for healthy status in patients with COPD seem to be independent of the modality or intensity of the exercise training undertaken.
