1. Introduction

Aldosterone is a mineralocorticoid hormone involved in renal sodium and potassium homeostasis and blood pressure modulation. Increased systemic and myocardial concentrations of aldosterone are associated with deleterious cardiac effects. Experimental studies have shown that aldosterone directly stimulates myocyte growth and strongly induces myocardial fibrosis [1,2]. The harmful effects of aldosterone on the cardiovascular system also include myocyte apoptosis, myocardial oxidative stress and electrical remodeling, vascular injury, endothelial dysfunction, ventricular arrhythmia, and sudden death [3,4]. After the pioneer studies by Pitt et al. [5–7], aldosterone antagonists started to be evaluated in different cardiac aggression models, which showed that they prevent or attenuate left ventricular (LV) structural, functional, and molecular changes [8–11]. In clinical settings, aldosterone blockers reduced mortality and hospitalizations in patients with systolic heart failure of any cause [5,7], and in patients with systolic dysfunction after myocardial infarction [6]. Therefore, aldosterone blockade is now recommended for symptomatic systolic heart failure patients [12]. In contrast, recent studies have shown that aldosterone blockade failed to reduce cardiovascular morbimortality [13] or improve maximal exercise capacity, symptoms, or quality of life in heart failure patients with preserved ejection fraction [14]. The mechanisms responsible for the lack of response to aldosterone blockers in this situation are not clear.

Chronic pressure overload is a major cause of heart failure with preserved or reduced ejection fraction. During sustained pressure overload, cardiac remodeling is mainly characterized by myocyte hypertrophy and interstitial fibrosis [15,16]. Stable cardiac hypertrophy is usually maintained for a long period and may progress to a decompensated
state with left ventricular dilation and systolic dysfunction [17,18]. The role of aldosterone antagonism on the development of cardiac hypertrophy during persistent pressure overload is not clear. In spontaneously hypertensive rats with LV hypertrophy and no heart failure features, aldosterone antagonist spironolactone reduced the frequency of heart failure development, improved myocardial function, and attenuated myocardial fibrosis independent of blood pressure levels [8]. In this study we tested the hypothesis that early aldosterone blockade improves cardiac remodeling during chronic pressure overload. Therefore, we evaluated the effects of spironolactone on cardiac structures, ventricular and myocardial function, and myocardial fibrosis in rats when administration was initiated three days after ascending aortic stenosis induction. In this model, 3–4 week-old rats are subjected to a clip placement around the ascending aorta [19]. After clip placement, aorta diameter is preserved; as rats grow, stenosis progressively develops [20,21]. Therefore, spironolactone was started before LV hypertrophy was established.

2. Materials and methods

2.1. Experimental groups

Male Wistar rats weighing 80–100 g were purchased from the Central Animal House at Rotucat Medical School, UNESP. All animals were housed in a temperature controlled room at 23 °C and kept on a 12-hour light/dark cycle. Food and water were supplied ad libitum. All experiments and procedures were approved by the Animal Experimentation Ethics Committee of Rotucat Medical School, UNESP, SP, Brazil. The animals underwent median thoracotomy under anesthesia with intraperitoneal ketamine hydrochloride (50 mg/kg) and xylazine hydrochloride (10 mg/kg). Aortic constriction was induced by placing a 0.6 mm stainless-steel clip on the ascending aorta via a thoracic incision according to a previously described method [22]. Age-matched sham operated rats were used as controls. Three days after surgery, the rats were randomly assigned into three groups: Sham (n = 22), aortic stenosis (AS, n = 41) and aortic stenosis treated with spironolactone (AS-SPR, n = 36). Treatment was initiated three days after surgery and kept up for 18 weeks. Spironolactone was added to rat chow at a dosage of 20 mg/kg/day. At the end of the experimental period, rats were subjected to transthoracic echocardiogram and euthanized the next day.

2.2. Echocardiographic study

Cardiac structures and left ventricular (LV) function were evaluated by transthoracic echocardiogram using a commercially available echocardiograph (General Electric Medical Systems, Vivid 56, Tiran Carmel, Israel) equipped with a 5–11.5 MHz multifrequency transducer as previously described [23–25]. Rats were anesthetized by intramuscular injection with a mixture of ketamine (50 mg/kg) and xylazine (0.5 mg/kg). A two-dimensional parasternal short-axis view of the left ventricle (LV) was obtained at the level of the papillary muscles. M-mode tracings were obtained from short-axis views of the LV at or just below the tip of the mitral-valve leaflets, and at the level of the aortic valve and left atrium. M-mode images of the LV were printed on a black-and-white thermal printer (Sony UP-890MD) at a sweep speed of 100 mm/s. All LV structures were manually measured by the same observer (KO) according to the leading-edge method of the American Society of Echocardiography [26]. Values obtained were the mean of at least five cardiac cycles on M-mode tracings. The following structural variables were measured: LV diastolic and systolic dimensions (LVDD and LVSDD, respectively), LV diastolic and systolic posterior wall thickness (LVPSWT and LVSPSWT, respectively), aortic diameter (AO), and left atrium (LA) diameter. Left ventricular mass (LVM) was calculated using the formula [(LVDD + PWMT + SWT)3 – (LVDD2)3] × 1.04. Relative wall thickness (RWT) was calculated as 2 × PWMT / LVDD. LV mass function was assessed by the following parameters: endocardial fractional shortening (EFS), midwall fractional shortening (MWFS), posterior wall shortening velocity (PVSW), early and late diastolic mitral inflow velocities (E and A waves), E/A ratio, E-wave deceleration time (EDT), and isovolumetric relaxation time (IVRT).

2.3. Myocardial functional study

Two days after echocardiographic study, myocardial contractile performance was evaluated in isolated LV papillary muscle preparations as previously described [22,28]. Rats were anesthetized with pentobarbital sodium, 50 mg/kg, intraperitoneally, and decapitated. Hearts were quickly removed and placed in oxygenated Krebs–Henseleit solution at 28 °C. LV anterior or posterior papillary muscle was dissected free, mounted between two spring clips, and placed vertically in a chamber containing Krebs–Henseleit solution at 28 °C and oxygenated with a mixture of 95% O2 and 5% CO2 (pH 7.38). The composition of the Krebs–Henseleit solution in mM was as follows: 118.5 NaCl, 4.89 KCl, 1.25 CaCl2, 1.16 MgSO4, 1.18 KH2PO4, 5.20 glucose, and 25.88 NaHCO3. The spring clips were attached to a Kyowa model 1207–208 force transducer and a lever system, which allowed for muscle length adjustment. Preparations were stimulated 12 times/min at a voltage 10% above threshold. After a 60-min period, during which the preparations were permitted to shorten while carrying light loads, muscles were loaded to contract isometrically and stretched to the apices of their length-tension curves (Lmax). After a 5-min period, during which preparations performed isotonic contractions, muscles were again placed under isometric conditions, and the apex of the length-tension curve was determined. A 15 minute period of stable isometric contraction was imposed prior to the experimental period. One isometric contraction was then recorded for later analysis. The following parameters were measured from isometric contraction: peak of developed tension (DT, g/mm²), resting tension (RT, g/mm²), maximum rate of tension development (−dDT/dt, g/mm²/s), maximum rate of tension decline (−dDT/dt, g/mm²/s), and time to peak of tension (TPT). To evaluate contractile reserve, papillary muscle mechanical performance was evaluated at basal conditions and after the following isometric stimulation: post-rest contraction, extracellular Ca²⁺ concentration increase, and β-adrenergic agonist isoproterenol addition to the nutrient solution [29]. Papillary muscle cross-sectional area (CSA) was calculated from muscle weight and length by assuming cylindrical uniformity and a specific gravity of 1.0. All force data were normalized for the muscle CSA. After dissecting papillary muscle, atria and ventricles were separated and weighed. Atria and left and right ventricular weights were normalized to body weight.

2.4. Morphologic study

Transverse LV sections were fixed in 10% buffered formalin and embedded in paraffin. Five-micrometer-thick sections were stained with hematoxylin–eosin and collagen-specific sirius red (Cristal Red FBA in aqueous saturated picric acid) [30]. In each heart, at least 50 myocyte diameters were measured as the shortest distance between borders drawn across the nucleus. On average, 20 microscopic fields were used to quantify interstitial collagen fractional area. Perivascular collagen was excluded from this analysis. Measurements were performed using a Leica microscope (magnification 40×) attached to a video camera and connected to a computer equipped with image analysis software (Image-Pro Plus 3.0, Media Cybernetics, Silver Spring, MD, USA).

2.5. Myocardial hydroxyproline concentration

Myocardial hydroxyproline (HOP) concentration was assessed to estimate tissue collagen content. HOP was measured in LV tissue as previously described [31,32]. Briefly, the tissue was homogenized using a Speedvac concentrator SC 100 attached to a refrigerated concentration trap (TBL 100) and vacuum pump (VP 100, Savant Instruments, Inc., Farmingdale, NY, USA). Dry tissue weight was measured and samples were hydrolyzed overnight at 100 °C with 6 N HCl (1 mL/10 mg dry tissue). A 50 μL aliquot of hydrolysate was transferred to an Eppendorf tube and dried in the Speedvac Concentrator. One milliliter of potassium borate buffer (pH 8.7) was added to maintain constant pH and the sample was oxidized with 0.3 mL of chloramine T solution at room temperature for 20 min. The addition of 1 mL of 3.6 M sodium thioulate and thorough mixing for 10 s stopped the oxidative process. The solution was then saturated with 1.5 g KCl. The tubes were heated in boiling water for 20 min. After cooling to room temperature, the aqueous layer was extracted with 2.5 mL of toluene. One and a half milliliters of toluene extract were transferred to a 12 × 75 mm test tube. Then 0.6 mL of Ehrlich’s reagent was added and the color allowed to develop for 30 min. Absorbances were read at 565 nm against a reagent blank. Deionized water and 20 μg/mL HOP were used as the blank and standard, respectively.

2.6. Metalloproteinase activity

Matrix metalloproteinases (MMP)-2 and -9 activity was determined as previously reported [33]. In brief, analysis samples were prepared by dilution in extraction sample buffer with 50 mM Tris, pH 7.4; 0.2 M NaCl; 0.1% Triton X, and 10 mM CaCl2. In sample protein was quantified by the Bradford method. Samples with 20 μg of protein were then diluted in application buffer with 0.5 M Tris, pH 6.8; 100% glycerol, and 0.05% bromophenol blue, and loaded into wells of 8% SDS-polyacrylamide containing 1% gelatin. Electrophoresis was run in a Bio-Rad apparatus at 80 V for 2 h. Gel was removed, washed twice with 2.5% Triton-X-100, and washed with 50 mM Tris, pH 8.4. Gel was then incubated at 37 °C overnight in activation solution with 50 mM Tris, pH 8.4; 5 mM CaCl2, and ZnCl2. Staining was performed for 2 h with 0.5% coomassie blue and destaining in 30% methanol and 10% acetic acid at room temperature until clear bands over a dark background were observed. The gels were photographed and the intensity of gelatinolytic action (clear bands) was analyzed in UVP, UV, White Darlkon image analyzer.

2.7. Statistical analysis

Data are expressed as mean ± standard deviation or median and 25th and 75th percentiles. Comparisons between groups were performed by one way analysis of variance (ANOVA) followed by Tukey test or Kruskal–Wallis followed by Dunn test. Mortality was assessed by log-rank test (Kaplan Meier). Statistical significance was accepted at the level of p < 0.05.
3. Results

During the experiment, AS and AS-SPR groups had mortality rates of 51.2% and 41.7%, respectively (p = 0.28). No rat from Sham group died during the experimental period. Body weight (BW) and anatomic parameters are shown in Table 1. Final body weight was lower in AS and AS-SPR than Sham. LV and atria weight, in absolute or normalized to body weight values, and right ventricle weight were higher in AS and AS-SPR than Sham and higher in AS-SPR than AS. In rats, the increase in atria weight and particularly the right ventricle weight are strong predictors of heart failure [34,35]. Therefore, the higher atria and right ventricle weight in AS-SPR suggests that spironolactone induced a more severe degree of heart failure.

Aldosterone antagonist doses vary between different experimental studies [36–38]. In previous works, we have observed that 20 mg/kg/day of spironolactone does not reduce arterial blood pressure in normotensive (data not shown) or hypertensive rats [8,39]. In addition, lower doses such as 10 mg daily of spironolactone had beneficial cardiovascular effects [37]. As the purpose of this study was to use a dose associated with cardiovascular effects but with no change in blood pressure, the rats received 20 mg/kg/day of spironolactone. After subjecting young rats to ascending stenosis, heart failure and ensuing death usually start to occur 18–22 weeks after surgery [20,22,40]. Therefore, to avoid excessively high mortality rates, we established 18 weeks as the period to treat our rats.

Table 2 shows structural cardiac parameters and Fig. 1 shows illustrative LV M-mode echocardiograms. LV diastolic diameter-to-body weight ratio, LV walls thickness, left atrial diameter, LV mass, and LV relative thickness were higher in AS and AS-SPR than Sham. LV diastolic (Sham 4.57 ± 0.67; AS 3.61 ± 1.49; AS-SPR 4.62 ± 1.48 mm) diameters, left atrial diameter (Sham 5.80 ± 0.44; AS 7.15 ± 1.22; AS-SPR 8.02 ± 1.17 mm), and LV mass were higher in AS-SPR than AS. Table 3 shows LV functional parameters. Endocardial fractional shortening was higher in AS than Sham. E wave was higher and E-wave deceleration time and isovolumetric relaxation time lower in AS and AS-SPR than Sham. Posterior wall shortening velocity (Sham 38.5 ± 3.8; AS 35.6 ± 5.6; AS-SPR 31.1 ± 3.8 mm/s) was lower in AS-SPR than Sham and AS; E/A ratio was higher in AS-SPR than Sham.

Table 4 shows basal papillary muscle data. Developed tension and +dT/dt were lower and resting tension higher in both AS and AS-SPR than Sham. Time to peak tension was higher in AS-SPR than Sham. Contractile reserve was evaluated after positive inotropic stimulation (Table 5). The + dT/dt was lower in AS and AS-SPR than Sham after all inotropic stimulation. Developed tension did not differ between groups after post-rest contraction and extracellular calcium increase to 2.5 mM, and was lower in AS and AS-SPR than Sham after isoproterenol addition to nutrient solution. Time to peak tension was higher in AS-SPR than Sham after all inotropic stimulation and was higher in AS-SPR than AS after post-rest contraction [Sham 165 (160–170); AS 168 (165–180); AS-SPR 188 (175–195) ms]. LV morphometric and biochemical data are shown in Table 6. Myocyte diameters were higher in AS and AS-SPR than Sham and did not differ between AS and AS-SPR. Intersitial collagen fractional area (Sham 2.29 ± 0.77; AS 5.13 ± 3.37; AS-SPR 3.14 ± 3.25%; Fig. 2) and myocardial hydroxyproline concentration were higher in AS than Sham; in AS-SPR, these parameters had values between those of the Sham and AS groups and did not differ significantly from either group. Metalloproteinase-2 and -9 activity did not differ between groups.

4. Discussion

In this study, we observed that early administration of aldosterone antagonist spironolactone unexpectedly increased cardiac hypertrophy and dilation, and impaired LV function in rats with aortic stenosis-induced chronic LV pressure-overload.

Ascending aortic stenosis in rats has been used to promote the gradual development of LV pressure overload and hypertrophy, similarly to human chronic pressure overload. In this model, a clip is placed around the ascending aorta in 3–4 week-old rats. Immediately after clip placement aorta diameter is preserved; as rats grow, stenosis and LV hypertrophy progressively develops [20–22]. Rats remain compensated for approximately 18 to 28 weeks [41]. In this study, spironolactone was initiated three days after surgery; therefore, the aldosterone blockade was started before the development of LV hypertrophy.

The addition of spironolactone to rat chow did not change food intake as AS and AS-SPR groups had similar body weights at the end of the experiment. Body weight was approximately 13.5% lower in AS and AS-SPR than Sham, showing the occurrence of cardiac cachexia and the severity of cardiac injury. Cardiac cachexia has been considered an independent predictor of mortality [41] and has been well characterized in rats with aortic stenosis–induced heart failure [42]. Probably due to the small sample size to evaluate mortality, this parameter did not significantly differ between AS and AS-SPR groups.

The echocardiographic study showed that both aortic stenosis groups presented left atrial dilation and LV concentric hypertrophy. The increased E and decreased E-wave deceleration time and isovolumetric relaxation time in AS and AS-SPR are in accordance with the anatomic parameters indicating higher filling pressures [43]. Hypertrophy in ascending aortic stenosis is usually better adaptive than in
worse systolic function than AS, characterized by its reduced PWSV and diastolic function, characterized by a higher E/A ratio. The more highly impaired systolic function in AS-SPR than AS was reinforced by endocardial fractional shortening, which was higher in AS than Sham, showing better systolic function in AS. In AS-SPR, this parameter had values between those in Sham and AS groups and did not significantly differ from either group, further characterizing the impairment of systolic function with spironolactone. Anatomical data confirmed greater LV hypertrophy and also showed greater right ventricular hypertrophy in AS-SPR than AS. In rats with LV pressure overload, right ventricular hypertrophy is considered a strong marker of LV failure and has been characterized by a right ventricle weight-to-body weight ratio greater than 0.8 mg/kg [34,35]. Therefore, our data suggest that the AS-SPR group presented a more advanced degree of heart failure than AS.

As aldosterone is a potent fibrosis inducer, we quantified myocardial fibrosis by histologic and biochemical analysis. The AS had a higher interstitial collagen fractional area and hydroxyproline concentration than Sham, and in AS-SPR these parameters had values between those of the Sham and AS groups, being statistically similar to each group. These data suggest that spironolactone may have attenuated the development of myocardial fibrosis.

Matrix metalloproteinases are proteolytic enzymes responsible for extracellular matrix component degradation. MMP activation can occur in response to many stimuli including neurohormonal stimulation and myocardial stretching and precedes ventricular dilation in different

cardiac injury models [45,46]. In ventricular myocyte culture, aldosterone stimulates MMP activity [47], and in patients with ischemic heart failure, spironolactone reduces MMP-9 serum activity [48]. However, in this study we did not observe differences in MMP-2 or −9 activation between groups. As we only evaluated MMP activation at the end of the experiment, we cannot exclude the influence of increased MMP activity during cardiac remodeling.

Most experimental studies have shown that aldosterone blockade has beneficial effects in different cardiac injury models. In pressure overloaded-induced cardiac remodeling, beneficial effects on different aspects of remodeling were observed when aldosterone blocker was initiated after LV hypertrophy had been established [9,10,49]. As aldosterone induces myocyte growth [2], we expected that aldosterone blockade would reduce cardiac hypertrophy. In fact, Pitt et al. [50] showed that aldosterone blocker eplerenone decreased LV hypertrophy in patients with systemic arterial hypertension. On the other hand, in patients with moderate-to-severe aortic stenosis, eplerenone did not change ventricular mass or the period without ventricular dysfunction [51].

Systolic wall stress can be calculated as intraventricular systolic pressure × cavity radius / 2 (LV wall thickness) [52]. When LV pressure is chronically increased, ventricular hypertrophy is initially important for reducing afterload and maintaining systolic function in the face of elevated intraventricular systolic pressure [52]. Cardiac hypertrophy is often accompanied by interstitial myocardial fibrosis. However, the role of hypertrophy and myocardial fibrosis during chronic pressure overload remains controversial [15,16]. These processes have been considered to have both beneficial and deleterious effects, according to stimulation characteristics such as overload intensity and duration, and onset severity [15].

In this study, spironolactone caused more maladaptive hypertrophy with more dilation, increased filling pressures, and more pronounced right ventricular hypertrophy, suggesting that spironolactone may be deleterious during early chronic pressure overload. The essential involvement of aldosterone in ventricular growth and development at an early age has not been established. We have not identified any studies evaluating the effects of early aldosterone blockade during chronic pressure overload. However, in different experimental models of transgenic or induced myocardial fibrosis inhibition, aortic banding was followed by reduced myocardial fibrosis and increased end-diastolic pressure or LV dilation [53–55]. Thus, our data and these results from literature allow us to hypothesize that, after elevation in LV pressure, the increase in myocardial interstitial collagen tissue is important in preventing ventricular chamber dilation. By inhibiting interstitial fibrosis, spironolactone may have facilitated ventricular dilation to occur early during chronic pressure overload. Ventricular dilation, per se, may be responsible for the impaired LV systolic and diastolic functions observed in the AS-SPR group. The papillary muscle preparations allow us to analyze myocardial function and contractility independent of the influence of afterload and preload. Data from papillary muscle functional study reinforces this hypothesis as, except for the increased time to peak of tension, myocardial contractility at basal conditions and after positive inotropic stimulation did not differ between AS-SPR and AS groups. Currently, as several drugs to prevent or reverse myocardial fibrosis are under investigation, it is important to better understand the role of connective tissue and fibrosis during the early phase of chronic pressure overload.

A limitation of this study refers to the fact that cardiac remodeling was only evaluated at the end of the experiment. Additional studies with different evaluation periods and detailed molecular analysis will be helpful in clarifying the physiopathological mechanisms involved in the effects of aldosterone blockade during early pressure overload. Furthermore, in this study, aortic stenosis was induced in young rats. As the hypertrophic response to a pressure overload present at birth may differ from the response to one acquired later in life [56], additional research is needed to establish whether our results are applicable to later acquired

Data are mean ± standard deviation or median and 25th and 75th percentiles. Sham: control sham-operated rats; AS: aortic stenosis; AS-SPR: aortic stenosis treated with spironolactone; DT: peak of developed tension; +dT/dt: maximum rate of tension development; TPT: time to peak of tension; PP60: post-restraction after a 60 s pause; 2.5 mM Ca²⁺/[Ca²⁺]₀: isometric contraction at 2.5 mM extracellular calcium concentration; 10⁻⁶ M Iso: isometric contraction with 10⁻⁶ M isoproterenol added to the nutrient solution. ANOVA and Tukey or Kruskal-Wallis and Dunn.

* p < 0.05 vs Sham.

Data are mean ± standard deviation or median and 25th and 75th percentiles. Sham: control sham-operated rats; AS: aortic stenosis; AS-SPR: aortic stenosis treated with spironolactone; CFA: interstitial collagen fractional area; HOP: hydroxyproline; MMP-2 and MMP-9: metalloproteinase-2 and -9, respectively (n = 7 per group). ANOVA and Tukey or Kruskal-Wallis and Dunn.

* p < 0.05 vs Sham.
aortic stenosis. Nonetheless, caution is warranted when prescribing al-
dosterone blockers to patients in an early stage of aortic stenosis.

In conclusion, early administration of aldosterone antagonist
spironolactone causes further hypertrophy in cardiac chambers, and
left ventricular dilatation and dysfunction without changing myocardial
function in rats with aortic stenosis-induced chronic pressure overload.

Conflict of interest

The authors report no relationship that could be construed as a con-
flict of interest.

Ethical statement

We adhere to the statement of ethical publishing as appears in the
International Journal of Cardiology [57].

Grants

Financial support was provided by CNPq (308674/2015-4, 306770/
2015-6, 479085/2013-7, 480829/2013-6), FAPESP (2009/54506-7,
2015/17539-5), CAPES, and PROPe, UNESP.

Acknowledgments

The authors are grateful to Jose Carlos Georgette for their technical
assistance and Colin Edward Knaggs for English editing.
