Hydroxymethylfurfural
Diffuse reflectance spectroscopy

A B S T R A C T

Cachaça is the popular name of sugarcane liquor obtained from fermented sugarcane mash broth. This is one of the most popular alcoholic beverages in Brazil and is gaining ground in the global market. One of the quality parameters established by Brazilian law is the sum of the concentrations of furfural and hydroxymethylfurfural, two compounds that give the beverage an unpleasant taste and have mutagenic potential. These two substances are usually determined by chromatographic techniques that employ toxic organic solvents that can be damaging to the health of the operator and to the environment. This paper describes the development of a new methodology to determine furfural and hydroxymethylfurfural in sugarcane liquor using a diffuse reflectance technique coupled with limited-area spot-testing on a paper platform. The new method presented LOQ values of 0.74 mg L$^{-1}$ for furfural and 1.27 mg L$^{-1}$ for hydroxymethylfurfural. Recoveries in the ranges 89.5–106% (furfural) and 96.3–106% (hydroxymethylfurfural) indicated that there was no significant influence of the matrix in determination of the analytes. The method was applied using eleven sugarcane liquor samples from different locations in Brazil.

1. Introduction

Sugarcane liquor is one of the most common alcoholic beverages in Brazil and is increasingly popular worldwide. It is also known by the names “sugarcane spirit” or “cachaça”. In 2016, it was exported to over 40 countries, generating revenues of about US$ 13.9 million [1].

This drink is obtained by distilling fermented sugarcane mash, and one of the quality parameters established by the Ministry of Agriculture, Livestock and Supply (MAPA) is the sum of the concentrations of furfural (FUR) and hydroxymethylfurfural (HMF), with a maximum limit of 5 mg in 100 mL of anhydrous ethanol [2]. Unlike many contaminants, the formation of FUR and HMF not only occurs in the fermentation step; both substances can be produced in the broth if the harvesting is preceded by the burning of the sugarcane plants, which can lead to the generation of free sugars such as pentoses and hexoses in the broth. The degradation of the free sugars then results in the formation of FUR and HMF. These compounds are markers of heating processes in many products that contain sugars in their composition [3–7], and their presence in sugarcane liquor is undesirable because it gives the beverage unwanted features such as a penetrating and nauseating aroma [8]. Furthermore, due to the planarity of their structures (Fig. 1), FUR and HMF are potentially carcinogenic/mutagenic since they can interact with DNA molecules [9–15].

Several methodologies are available for the determination of FUR and HMF in many types of samples, mostly based on chromatography [16–20]. Although these techniques provide efficient separation and determination of the analytes, with low limits of detection, disadvantages are that they usually require the use of toxic organic solvents and that the instruments employed for the analyses are expensive and require specialist operators. The method involving electrophoretic separation [21] offers an analysis without organic solvent, but the instrumentation required has higher added cost, compared to the equipment needed in the analytical method proposed here, and also necessitates a specialized operator. The methodology with digital image detection [22] is an example of an analytical procedure that reduces the use of reagents and generates lower quantities of waste, compared to conventional procedures [2]. Nevertheless, the spot method [22] used only determines the furfural concentration, rather than the sum of HMF and FUR as required by legislation [2]. Therefore, for samples in which the amount of HMF and FUR exceeds the established limit, the FUR concentration could be below this limit (as in the case of sample G), generating a false negative. With the volume required for only one determination by the digital image procedure [22], it would be possible to perform around 40 analyses using the proposed method. In addition, the waste generated in the present method is solid and readily incinerable, while in the method proposed by Franco et al. [22], the residues produced have to be converted to harmless substances.

In most cases, analytical methodologies do not conform to the principles of Green Chemistry [23], which aims to minimize (or preferably...
eliminate) the use of toxic organic solvents and develop simpler and less onerous methodologies. A good alternative method for the determination of FUR and HMF is diffuse reflectance spectroscopy, which is simpler than the chromatographic techniques usually used to analyze such compounds.

For many years, the use of reflectance spectroscopy was limited to paints and pigments, paper, textile areas, ceramics, dye-stuffs and printing inks to evaluate properties such as color, whiteness, gloss, covering power, and so on [24]. Recently with the development of optical devices such as integrating sphere assemblies, diffuse reflectance spectroscopy is rapidly gaining in acceptance in analytical chemistry. Application of diffuse reflectance spectroscopy especially associated to spot test has been reported in the literature indicating the potential of this technique for quantitative analysis [25-27].

In the present work, we describe a new spot test/diffuse reflectance spectroscopy method employing a paper platform delimited with hydrophobic barriers. The combination of diffuse reflectance spectroscopy and spot testing is eco-friendly because it uses minimal quantities of reagents and consequently generates only minor amounts of waste, while the environmental and health risks are very low [23]. Filter paper is obtained from renewable sources and provides an excellent platform for spot tests due to its cellulose fiber composition and its white color, which provides a bright and high contrast background [24].

The use of hydrophobic barriers for impregnation of the filter paper platforms used in spot tests greatly improves the analyses by preventing the analyte and reagent solutions from eluting beyond the area defined by the barrier [28], hence increasing the concentration of the colored product and the magnitude of the analytical signal. The first report of the use hydrophobic barriers was in the work of Yagoda in 1937 [29], for determination of metal ions, and since then several papers have described the use of hydrophobic barriers in inexpensive and portable methodologies [30-32].

There are many ways to impregnate the hydrophobic barriers in the paper platform [31]. One method is wax printing, where a wax-based printer prints patterns of solid wax on the surface of the paper, followed by heating in an oven or on a hotplate [28]. When the wax ink is heated, it penetrates through the porous paper, creating the hydrophobic barriers that prevent the solution eluting beyond the delimited area.

2. Experimental

2.1. Apparatus

Diffuse reflectance measurements were made using a portable spectrophotometer (USB2000, Ocean Optics) controlled with OOIBase32 software (Ocean Optics). The spectrophotometer was coupled to an integrating sphere using an optical fiber. The comparative method employed a Shimadzu UFLC-20A HPLC system with a DAD detector [17].

A mass spectrometer (Thermo Scientific LCQ Fleet Ion Trap LC/MS®) was used to determine the product structure.

2.2. Materials, reagents, and solutions

Whatman No. 1 qualitative filter paper was used as the solid support in the spot tests. All the reagents employed were analytical grade and were used without any prior purification. Analytical standards of furfural and hydroxymethylfurfural were obtained from J.T. Baker. Ultrapure water (18 MΩ cm, Milli-Q system, Millipore) was used to prepare the solutions.

The reagent solutions were composed of a mixture of p-aminobenzoic acid (Henrifarma, Brazil), barbituric acid (Merck), and hydrochloric acid (Merck), at different concentrations for the determinations of HMF or FUR.

Stock standard solutions of 0.00550 mol L−1 HMF and 0.00723 mol L−1 FUR were freshly prepared in aqueous 40% (v/v) solution of HPLC grade ethanol (J.T. Baker). Working solutions of FUR and HMF were prepared daily by appropriate dilutions of the stock solutions in aqueous 40% (v/v) ethanol.

2.3. Samples

Eleven sugarcane liquor samples were used to evaluate the performance of the new method proposed here. The liquor samples were either sugared (B, C, D, F, I, and J) or non-sugared (A, E, G, H, and K), and were also classified as aged (G and H) or non-aged (A, B, C, D, F, I, J, and K). The samples originated from the states of São Paulo (A, B, C, D, E, F, G, and H), Paraná (I), Pernambuco (J), and Ceará (K).

2.4. Procedure

2.4.1. Paper platform for spot tests

CorelDRAW ×5 was used to design hydrophobic barriers that were 15 mm in diameter and 0.75 mm in thickness. The design was printed onto Whatman No. 1 filter paper with wax toner (Genuine Xerox Solid Ink Black) using a wax printer (Xerox Phaser 8560), as described by Carrilho et al. [28]. After printing, the paper was heated for 120 s at 120 °C for formation of the hydrophobic barriers.

2.4.2. Reagent solution

The reagent solution, described in the work of Castoldi et al. [33], was based on the Winkler method for determination of HMF in honey samples [34]. This solution contained p-aminobenzoic acid (PABA), barbituric acid (BA), and hydrochloric acid (HCl). The analytes were quantified separately using two different reagent solutions, both composed of PABA, BA, and HCl, but at different concentrations, using a single spot test device for each analysis. The results were calculated as the sum of FUR and HMF.
2.4.3. Optimization of variables

Since the sample medium consisted essentially of water and ethanol, it was necessary to determine the ethanol percentage that provided the best analytical response. The percentages tested were 35, 40, 45, 50, and 55% (v/v) ethanol in water.

In preliminary tests, the effect of the pH of the reagent solution was studied using buffer solutions in order to improve the analytical response. Phosphate buffer was used for a neutral medium (pH 7.2). An acid medium (pH 4.5) was obtained using acetic acid, and an alkaline medium (pH 9.0) was obtained using ammonium buffer. The pH of deionized water (pH 6.5) was also used.

A full factorial design was employed to identify the main parameters to be optimized, using Statistica 7 software. For both analytes, the parameters evaluated were the concentrations of PABA, BA, and HCl.

The main parameters were used to construct response surfaces in order to find the optimal conditions for the two analytes. In the case of FUR, the parameters optimized were the PABA and HCl concentrations, while for HMF, the parameters optimized were the BA and HCl concentrations. The response surfaces were constructed using Statistica 7 software.

2.4.4. Comparative method

The results obtained with the new methodology proposed here were validated by comparison with the results obtained using the methodology described by Alcázar et al. [17]. The chromatographic separations were performed at 35 °C on a C-18 column (250 × 4.6 mm, 5 μm particle size), with isocratic elution using a mobile phase consisting of a mixture of acetonitrile (ACN) and an acid solution (acetic and phosphoric acids, 18:82), at a flow rate of 1.2 mL min⁻¹. The detection wavelength was 280 nm.

2.4.5. Products structure

In order to confirm the products formed from the reaction involving PABA, BA, and FUR, a solution containing the analyte and reagents was analyzed using mass spectrometry in full scan negative mode. The operating conditions were a capillary voltage (ESI) of 5 kV, N₂ flow rate of 8 (arbitrary units), transfer capillary temperature of 275 °C, transfer capillary voltage of 11 V, and sample solution flow rate of 5 μL min⁻¹.

3. Results and discussion

3.1. Preliminary tests

The reagents selected for the colorimetric determination of FUR and HMF were PABA and BA, based on earlier work by our research group [33]. In this reaction, there is cleavage of the furanic ring, forming a product that absorbs radiation in the visible region, as represented in Fig. 1.

It can be seen from Fig. 2 that there is no spectral interference between the products. Fig. 2A shows a representation of both products using the specific reagent for furfural determination; the blue product has an absorption maximum at 616 nm (red line), while the hydroxymethylfurfural product (which would have a yellow coloration, black line) shows no analytical signal at this wavelength. The same applies using the specific reagent for HMF determination (Fig. 2B), in which is used the specific reagent for HMF determination; the characteristic yellow product presents an absorption maximum at 420 nm (black line), but when the HMF reagent for FUR determination is used, the product does not present any absorption (red line). Therefore, the use of a specific reagent for each analyte enables the determination of each of them without any interference from the other.

Evaluation was made of the influence of the order of addition of the reagent and analyte. It was found that the analytical response was greater and the color of the spot was more homogeneous when the reagent solution was added first, followed by the analyte solution. In the spot test, 15 μL amounts of each reagent and analyte solutions were applied to the center of the delimited area.

An increase of approximately 30% in the signal was achieved when the spot area was delimited by the hydrophobic barriers, compared to an absence of barriers, due to the confinement of the solution within a limited space, bounded by the hydrophobic barriers. When the area was delimited, the standard deviations were smaller and the colors were sharper and more uniform.

3.2. Optimization of experimental conditions

The results of the tests showed that the percentage of ethanol did not significantly influence determination of the analytes. A percentage of 40% (v/v) was therefore selected, because the most of the samples had alcohol contents of 38–39%.

The tests to evaluate the influence of the pH of the reagent solution showed that an acid pH provided better responses for both analytes. However, after performing the experimental design, it was found that lower pH values were required, so a standardized HCl solution was used in subsequent analyses. A low pH was necessary to promote cleavage of the furanic ring, resulting in formation of the colored product.

The results obtained using the full factorial design (Table S1) showed that assay #6 (maximum value of PABA, minimum values of BA and HCl) presented better analytical responses for both analytes. The Pareto chart for FUR (Fig. S1A) showed that the PABA and HCl concentrations had the greatest influence on the measurement, with higher amounts of these two compounds resulting in a better analytical response. For HMF determination, the parameters that had the greatest influence

![Fig. 2](image-url)
were HCl and BA, with higher amounts of HCl and lower amounts of BA resulting in a higher signal (Fig. S1B). It should be noted that PABA and BA must be present in the reactions used to determine the analytes, because if either of these reagents was absent, there was no formation of the characteristic colored products.

After determination of the most significant parameters for each analyte, individual response surfaces were constructed for the FUR and HMF reactions, with the aim of identifying the optimal experimental conditions and maximizing the analytical response. In the case of the FUR response surface, the parameters evaluated were the PABA and HCl concentrations, while for the HMF response surface, the concentrations of HCl and BA were evaluated. Table S2 provides the conditions of the response surfaces, together with the results obtained in each assay.

Fig. 3 illustrates the response surface graph for HMF, obtained from the fitting of the experimental data described in Table S2. The quadratic regression model describing the response surface graph is given by the following equation:

\[ A_R = 0.141 + 0.119[HCl] - 0.439[HCl]^2 + 20.418[BA] - 667.926[BA]^2 + 6.500[HCl][BA] \]

The HMF response surface (Fig. 3) showed a maximum point that identified the experimental conditions at which the maximum analytical response was achieved. The optimum concentrations of BA and HCl were 0.017 and 0.27 mol L\(^{-1}\), respectively. Since the PABA concentration had only a minor influence on the HMF determination, the value that gave the best response in the factorial design tests was chosen (0.011 mol L\(^{-1}\)).

Fig. 4 shows the response surface for the FUR reaction. The quadratic regression model is given by:

\[ A_R = 0.005 + 0.625[HCl] - 89.083[HCl]^2 + 6.511[PABA] - 45.889[PABA]^2 + 47.222[HCl][PABA] \]

It can be seen that no maximum point corresponding to the optimal analysis conditions was achieved. Analysis of the response surface suggested that this was due to the need to increase the PABA concentration. However, this was not possible, since there was a limit to the solubility of PABA in the reagent solution. Hence, the maximum possible amount of PABA was used (0.054 mol L\(^{-1}\)). In the case of the HCl concentration, the optimum value (0.015 mol L\(^{-1}\)) was achieved, as can be seen in Fig. 4. For the BA concentration, the value used was 0.017 mol L\(^{-1}\), which has been found to provide the best analytical response in previous studies. Optical stability tests were performed in order to determine the times during which the reaction products remained stable under ambient conditions, after the spot test substrates had dried. Both products were found to be stable from 15 to 120 min after the reactions.

3.3. Figures of merit

After optimization of the experimental conditions, analytical curves were constructed for both analytes. For FUR, the linear range used was from 8.69 × 10\(^{-6}\) mol L\(^{-1}\) to 4.17 × 10\(^{-4}\) mol L\(^{-1}\), while for HMF, the linear range used was from 1.10 × 10\(^{-5}\) mol L\(^{-1}\) to 7.91 × 10\(^{-4}\) mol L\(^{-1}\). Linear relationships were found between the analytical responses (\(A_R\)) and the square roots of the analyte concentrations (\(C^{1/2}\)). The linear regression equation for HMF was \(A_R = 15.822(C_{\text{HMF}})^{1/2} - 0.0263\), with correlation coefficient (\(R\)) equal to 0.998. For FUR, the equation was \(A_R = 27.117(C_{\text{FUR}})^{1/2} - 0.027\), with \(R = 0.997\). As Ghauch and co-workers pointed out, the analytical response does not necessarily show a direct linear relationship with the analyte concentration; the relation between these two parameters may be mathematically described by many types of plots, for example \(A_R\) vs \(\log C\) and \(A_R\) vs \(C^{1/3}\) [35,25]. In the present case, a linear relation between analytical response and analyte concentration was obtained using \(A_R\) vs \(C^{1/2}\), as also found by Rossini et al. [27].

The repeatability of the proposed method was evaluated using the relative standard deviations (%RSD) obtained for intra-day and interday tests [36] at two different concentrations. For a 5 mg L\(^{-1}\) solution of FUR, the values obtained were 3.4% (intra-day) and 3.7% (interday), while for a 40 mg L\(^{-1}\) solution, the values found were 1.1% and 1.8%, respectively. For a 5 mg L\(^{-1}\) HMF solution, the intra-day and inter-day repeatability values were 3.2% and 5.5%, respectively, while for a 20 mg L\(^{-1}\) HMF solution, the values were 2.4% and 2.6%, respectively. These values were considered acceptable [37] and demonstrated...
that the method proposed here is repeatable and can be used for FUR and HMF analyses.

The LOD and LOQ values were determined according to the IUPAC recommendations [38]: LOD = \(3\sigma/S\) and LOQ = \(10\sigma/S\), where \(\sigma\) is the standard deviation of measurements of the blank (\(n = 10\)) and S is the slope of the linear range. For FUR, the values found were \(6.93 \times 10^{-7}\) mol L\(^{-1}\) (0.067 mg L\(^{-1}\)) and \(7.70 \times 10^{-6}\) mol L\(^{-1}\) (0.740 mg L\(^{-1}\)), respectively. For HMF, the values found were \(9.03 \times 10^{-6}\) mol L\(^{-1}\) (0.114 mg L\(^{-1}\)) and \(1.00 \times 10^{-5}\) mol L\(^{-1}\) (1.27 mg L\(^{-1}\)), respectively. The LOD and LOQ values were therefore appropriate for the determination of FUR and HMF by the proposed method.

### 3.4. Recovery tests

In order to evaluate the influence of the matrix, recovery tests were performed using two types of samples: a non-sugared aged sample and a sugared sample that had not been aged. Both types of samples were fortified with FUR and HMF at levels ranging from 7.60 to 35.0 mg L\(^{-1}\) for FUR and from 13.1 to 45.9 mg L\(^{-1}\) for HMF. For the first type of sample, the recovery values were between 93.0% and 108% for FUR and between 96.2% and 102% for HMF. For the second type of sample, the recoveries were between 89.5% and 106% for FUR and between 100% and 106% for HMF. These results showed that none of the sample matrices had any significant influence on the FUR and HMF determinations. Besides, this test demonstrated that compounds commonly present in sugarcane liquid samples, as sucrose, higher alcohols, ethyl carbamate, acetic acid, ethyl acetate and acetaldehyde, presented no interferences in the proposed method, demonstrating the selectivity of the reaction for HMF and FUR determination.

### 3.5. Determination of FUR and HMF in sugarcane liquor

The proposed method was applied using eleven samples (described in Section 2.3) and the results obtained were compared with those obtained by a method already described in the literature. We chose to use the chromatographic technique described by Alcázar et al. [17], reproducing the experimental conditions in our laboratory using a similar chromatographic system and column, as described in Section 2.4.4.

The concentrations of FUR and HMF were determined separately and then summed to obtain the value required by legislation [2]. In order to achieve a better comparison of the methods, the results were compared analyte by analyte. In other words, the furfural results obtained for each method were compared to each other, as were the results obtained in the hydroxymethylfurfural analyses. Table 1 shows the results obtained for the two analytes and the different methods. For both FUR and HMF, the two methodologies gave similar values; with the Student’s t-test indicating that there were no significant differences between the techniques (the calculated t-values were lower than the tabulated t-values).

In the same Table 1 there is the sum of the FUR and HMF values (as required by Brazilian law) for the sugarcane liquors. Only one sample (C) showed a concentration higher than the permitted value, which was probably because caramel dye had been added in order to simulate an aged beverage. These results were indicative of the excellent quality of the Brazilian sugarcane liquors, which complied with the requirements for export and internal consumption.

A comparison of the proposed method and other methods found in the literature is provided in Table 2. The linear ranges and LOQ values of the new technique were suitable for the intended purpose and were superior to some of the earlier methods. The new method does not use toxic organic solvents (which are required in chromatographic analyses), the sample can be analyzed directly without pretreatment or dilution, and the equipment is low cost. It can be seen from Table 2 that for many types of samples, there is a lack of simultaneous determinations of these two compounds using portable and easily implemented methodologies. For example, the official quality parameter is the sum of the concentrations of furfural and hydroxymethylfurfural, but the image-based colorimetric method was only used to analyze furfural in sugarcane liquor. In addition, the proposed method shows adequate sensitivity for the determination of FUR and HMF in sugarcane liquid samples according to Brazilian law [2].

### 3.6. Determination of product structure

The structure of the colored product formed in the reaction involving PABA, BA, and HMF was described by Castoldi et al. [33] and is illustrated in Fig. 1A. In the present work, the solution of reagents and furfural was analyzed by mass spectrometry, using the conditions described in Section 2.4.5. Fig. S2 presents the fragmentograms of the products obtained in the reaction involving PABA, BA, and FUR. The structure of the product (Fig. 1B) is based on the work of Winkler [34], with PABA as a substance analogous to aniline.

The suggested product of the FUR reaction (Fig. 1B) has a molecular mass of approximately 343 g mol\(^{-1}\). The spectrum acquired in negative mode showed a base peak at \(m/z\) 342.00, corresponding to the molecular ion (M–1), in agreement with the proposed structure. The main peaks at \(m/z\) 299 and 256 represented the losses of CONH and 2(CONH), respectively. The other peaks in the spectrum were not relevant for determining the product structure. The fragmentation

4. Conclusions

The new method is effective for the determination of furfural and hydroxymethylfurfural in sugarcane liquors using a delimited spot test with diffuse reflectance detection. The hydrophobic barriers used in this work significantly increased the sensitivity of the method, without any need for heating or the use of toxic organic solvents. In comparison against a chromatographic technique, the proposed methodology was found to be precise, accurate, safer, cheaper, and more environmentally friendly, generating less waste material than the comparative method. The vast majority of the sugarcane liquor samples analyzed showed values for the sum of FUR and HMF that were below the limit imposed by law. The structures of the products formed in the reactions involving friendly, generating less waste material than the comparative method.

Honey Capillary Electrophoresis

4. Conclusions

The new method is effective for the determination of furfural and hydroxymethylfurfural in sugarcane liquors using a delimited spot test with diffuse reflectance detection. The hydrophobic barriers used in this work significantly increased the sensitivity of the method, without any need for heating or the use of toxic organic solvents. In comparison against a chromatographic technique, the proposed methodology was found to be precise, accurate, safer, cheaper, and more environmentally friendly, generating less waste material than the comparative method. The vast majority of the sugarcane liquor samples analyzed showed values for the sum of FUR and HMF that were below the limit imposed by law. The structures of the products formed in the reactions involving p-aminobenzoic acid, barbituric acid, and the analytes were confirmed by mass spectrometry analysis.

Acknowledgments

We would like to thank the National Council for Scientific and Technological Development (CNPq) and the Research Support Foundation of São Paulo State (FAPESP, process no 2015/21733-1) for financial support, and the Institute of Chemistry of UNESP (Araraquara, São Paulo, Brazil) for the use of facilities.
