# Measurement of the underlying event activity in pp collisions at $\sqrt{s} = 0.9$ and 7 TeV with the novel jet-area/median approach

---

**The CMS collaboration**

**ABSTRACT:** The first measurement of the charged component of the underlying event using the novel “jet-area/median” approach is presented for proton-proton collisions at centre-of-mass energies of 0.9 and 7 TeV. The data were recorded in 2010 with the CMS experiment at the LHC. A new observable, sensitive to soft particle production, is introduced and investigated inclusively and as a function of the event scale defined by the transverse momentum of the leading jet. Various phenomenological models are compared to data, with and without corrections for detector effects. None of the examined models describe the data satisfactorily.

**KEYWORDS:** Hadron-Hadron Scattering

## 1 Introduction

In the theoretical description of nondiffractive inelastic proton-proton collisions, the main momentum transfer occurs between only two partons. This simple picture is refined by the inclusion of radiative effects in the form of initial- and final-state radiation. In addition, the primary interaction is accompanied by the production of further particles in multiple-parton interactions (MPIs) and in the hadronisation of the beam-beam remnants. The extra activity in a collision, which cannot be uniquely separated from initial- and final-state radiation, is referred to as the underlying event (UE).

Monte Carlo event generators simulate the UE based on phenomenological models, which have been tuned to the data of various collider experiments, taking into account the dependence of the UE on the centre-of-mass energy. The observation of substantial deviations of the predictions from the data, in particular when extrapolating to different

centre-of-mass energies, emphasises the need for measurements of the UE at different energies [1–6]. Retuned models allow for more precise measurements of observables based on jets or relying on isolation cones, for example in diphoton events from QCD processes or decays of the Higgs boson.

An unambiguous association of a specific particle to the reaction from which it originates is impossible. The investigation of the UE therefore requires a physically motivated separation of hard and soft contributions through the definition of phase-space regions that are dominated by either the hard or soft component of a collision. Traditionally, this is done by geometrically subdividing an event into different regions (“towards”, “away”, and “transverse”) with respect to the jet or particle leading in transverse momentum  $p_T$ . At the same time the  $p_T$  of the leading object is defined to be the so-called “event scale”, i.e. a measure of the momentum transfer in the hard partonic scattering. Studies using this approach were performed at the Tevatron [1–3] and the Large Hadron Collider (LHC) [4–6].

A new technique based on the transverse momentum density per jet area, the jet-area/median approach, was proposed in [7]. The jet area covered by a jet, the “catchment area” [8], is determined in the plane of pseudorapidity  $\eta$  versus azimuthal angle  $\phi$  as defined in section 2. The exact size and shape of the area must be sensitive to the event-by-event fluctuating soft hadronic activity of the UE. The most widely used jet algorithm at the LHC, the anti- $k_T$  jet algorithm [9], is unsuited for such an analysis and is replaced by the  $k_T$  algorithm [10–13]. The separation of the soft from the hard component of a collision is performed event by event by using the median of the distribution of transverse momentum densities of all jets in an event.

The data analysed in this study were collected with the Compact Muon Solenoid (CMS) detector at centre-of-mass energies of 0.9 and 7 TeV during the early LHC running in 2010, in which the contamination of events by additional proton-proton collisions in or close to the same bunch crossing, so-called pileup collisions, is very small. This jet area technique can be exploited to correct jet energies for pileup contamination in other measurements. The present paper is the first publication applying this new method in a collider experiment.

In the following, section 2 defines the UE-sensitive observable based on jet areas. Section 3 describes the experimental setup for data collection, triggering, vertex reconstruction, and event selection. Section 4 gives details on the phenomenological models used for event generation and on the detector simulation. The event reconstruction and the track and jet selections are explained in section 5 and are followed by a description of the unfolding technique in section 6. Sections 7 and 8 present the derivation of the measurement uncertainties and the final results, which are then summarised in section 9.

## 2 Definition of the observable

CMS uses a right-handed coordinate system, with the origin at the nominal interaction point, the  $x$  axis pointing to the centre of the LHC, the  $y$  axis pointing up (perpendicular to the LHC plane), and the  $z$  axis along the anticlockwise-beam direction. The polar angle

$\theta$  is measured from the positive  $z$  axis and the azimuthal angle  $\phi$  is measured in the  $x$ - $y$  plane. The pseudorapidity  $\eta$  is then defined as  $\eta = -\ln \tan(\theta/2)$ .

The adopted standard for jet clustering in the LHC experiments is the anti- $k_T$  jet algorithm [9]. Although it follows a sequential recombination procedure, the jets leading in  $p_T$  resemble in shape the jets reconstructed using algorithms with fixed cone sizes [14] because it starts clustering with the hardest (highest  $p_T$ ) objects. Hence, it is less sensitive to details of the distribution of softer objects in an event and less suited for an investigation of the UE. In contrast, the  $k_T$  jet algorithm clusters the softest objects first, trying to undo the effects of parton showering [10–12]. This approach to jet clustering leads to nonuniform catchment areas of  $k_T$  jets, which can be evaluated by applying the active area clustering technique as described in [8]. In this analysis of the UE, jets are reconstructed using the  $k_T$  algorithm with a distance parameter  $R$  of 0.6 as implemented in the FASTJET package [13, 15], which at the same time performs the jet-area determination. For this purpose, the event in question is overlaid with a uniform grid of artificial, extremely soft “ghost particles” in the  $\eta$ - $\phi$  plane as indicators of a jet’s domain of influence or catchment area. They are fed into the jet algorithm together with the measured tracks or charged particles but without impact on the reconstructed physical jets. This is guaranteed by the use of an infrared- and collinear-safe jet algorithm and the smallness of the transverse momentum of the ghost particles, which is of the order of  $10^{-100}$  GeV. The number of ghosts,  $N_j^{\text{ghosts}}$ , clustered into a jet  $j$  is then a measure of the jet area  $A_j$ :

$$A_j = \frac{N_j^{\text{ghosts}}}{\rho^{\text{ghosts}}} = \frac{N_j^{\text{ghosts}}}{N_{\text{tot}}^{\text{ghosts}}} A_{\text{tot}}, \quad (2.1)$$

where  $\rho^{\text{ghosts}}$  is the ghost density, defined as the total number of ghosts  $N_{\text{tot}}^{\text{ghosts}}$  divided by the total area  $A_{\text{tot}}$  within the acceptance. In this study,  $A_{\text{tot}}$  is set equal to  $8\pi$  according to the ranges of  $0 \leq \phi < 2\pi$  and  $|\eta| \leq 2$ . In order to limit boundary effects, the directions of the jets axes are restricted to  $|\eta| < 1.8$  while tracks are used up to  $|\eta| = 2.3$ . The distribution of ghosts extends up to  $|\eta| = 5$ . Here it is important to note that empty areas within the acceptance are covered by jets which consist solely of ghost particles. These “ghost jets” have a well-defined area but vanishing transverse momentum.

A measure of the soft activity in an event is then given by the median  $\rho$  of the distribution of the jet transverse momentum per jet area for all jets in an event [7]:

$$\rho = \text{median}_{j \in \text{jets}} \left\{ \frac{p_{Tj}}{A_j} \right\}. \quad (2.2)$$

The choice of the median is motivated by its robustness to outliers in the distribution. These outliers are in particular the leading jets originated by the hard partonic interaction. The observable  $\rho$  thus naturally isolates UE contributions by assuming that the majority of the event is either empty or dominated by soft contributions and that the hard component of the interaction is well contained within the leading jets. In contrast to the conventional approach, no explicit geometrical subdivision of the event is necessary. The separation of the hard and soft components is done event by event through the area clustering for the  $k_T$

algorithm and the use of the median. An advantage of this novel method is that it can easily be extended to event topologies other than the minimum-bias events investigated here.

In the proposal for a measurement of  $\rho$  in collider experiments [7], no kinematic selection was imposed on the input particles for the jet clustering. Unfortunately, this is not realistic experimentally because of threshold effects and a limited detector acceptance. Typically in minimum-bias events with a low average charged-particle multiplicity, large parts of the detector do not contain any physical particles and are therefore covered by ghost jets. As each ghost jet contributes one entry at  $p_{\text{T}j}/A_j = 0$ , events with a majority of ghost jets have  $\rho = 0$ , corresponding to zero UE activity. In order to increase the sensitivity to low UE activity, an adjusted observable  $\rho'$  is introduced, which takes into account only jets containing at least one physical particle:

$$\rho' = \underset{j \in \text{physical jets}}{\text{median}} \left\{ \frac{p_{\text{T}j}}{A_j} \right\} \cdot C. \quad (2.3)$$

Here, the event occupancy  $C$ , defined as the area  $\sum_j A_j$  covered by physical jets divided by the total area  $A_{\text{tot}}$ , is a measure of the “nonemptiness” of an event. While in  $\rho$  the ghost jets account for empty regions in the detector in the derivation of the median, the scaling factor  $C$  has a similar effect on  $\rho'$  by shifting events with low activity towards smaller values of  $\rho'$ . In the limit of full coverage of the detector with physical jets,  $\rho$  and  $\rho'$  are identical.

### 3 Detector description and event selection

The central feature of the CMS apparatus is a superconducting solenoid of 6 m internal diameter. Within the field volume are a silicon pixel and strip tracker, a crystal electromagnetic calorimeter, and a brass/scintillator hadron calorimeter. Muons are measured in gas-ionisation detectors embedded in the steel return yoke. Extensive forward calorimetry complements the coverage provided by the barrel and endcap detectors. In the following, only the parts of the detector that are most important for this analysis will be presented. A more detailed description can be found in ref. [16].

The inner tracker measures charged particles within the pseudorapidity range  $|\eta| < 2.5$ . It consists of 1440 silicon pixel and 15 148 silicon strip detector modules and is located in the 3.8 T field of the superconducting solenoid. It provides an impact parameter resolution of  $\sim 15 \mu\text{m}$  and a transverse momentum resolution of about 1.5% for 100 GeV particles.

Two subsystems of the first-level trigger system are used in this analysis: the Beam Pick-up Timing for eXperiments (BPTX) and the Beam Scintillator Counters (BSC). The two BPTX devices, which are installed around the beam pipe at a distance of  $\pm 175$  m from the interaction point, are designed to provide precise information on the structure and timing of the LHC beams with a time resolution better than 0.2 ns. The two BSCs, each consisting of a set of 16 scintillator tiles, are located along the beam line on each side of the interaction point at a distance of 10.86 m and are sensitive in the range  $3.23 < |\eta| < 4.65$ . They provide information on hits and coincidence signals with an average detection efficiency of 96.3% for minimum-ionising particles and a time resolution of 3 ns.

For an analysis of the UE, only data with not more than one collision per bunch crossing, i.e. without pileup, are suitable. Therefore data taken during periods with low instantaneous luminosity, between March and August 2010, at centre-of-mass energies of 0.9 and 7 TeV are used.

The high-level trigger selection requires at least one track to be reconstructed in the silicon pixel detector with a minimum transverse momentum of 0.2 GeV. This high-level trigger path is seeded by the BPTX and BSC level-1 triggers. In order to minimise the contamination caused by additional interactions within the same LHC bunch crossing, only events with exactly one reconstructed vertex are used in this analysis. The position of this vertex must be fitted from at least four tracks and its  $z$  component must lie within 10 cm of the centre of the reconstructed luminous region for the given data-taking run [17]. The effect of pileup collisions that remained undetected because of inefficiencies in the primary vertex reconstruction is estimated to be negligible compared to other sources of systematic uncertainty.

Even though this analysis contains data taken at two different centre-of-mass energies, all event selection and trigger criteria are identical throughout to guarantee compatibility of the results and consistency with the conventional UE measurement [4].

#### 4 Event generators and simulation

The generator predictions that are compared with the data were produced with three different tunes of the PYTHIA program version 6.4.22 [18], and one from PYTHIA version 8.145 [19]. The matrix elements chosen for the event generation reflect the minimum-bias event selection in data. A simulation of the CMS detector, based on the GEANT4 package [20], is applied. As Monte Carlo methods are used in both steps, we refer to “generator” when particle-level generator information is concerned, while “simulation” refers to a simulation of the CMS detector response.

The PYTHIA 6 tune D6T [21, 22] was the default tune within the CMS Collaboration prior to the LHC operation. It is based on the CTEQ6L1 [23] parton distribution functions (PDFs) and was tuned to describe measurements of the UA5 Collaboration at the Sp $\bar{p}$ S collider and the Tevatron experiments.

As a consequence of the higher particle multiplicities observed in LHC collision data at 0.9 TeV and 7 TeV [24–28] compared to existing model predictions, the new tunes Z1 [29] and Z2 were developed. Both tunes employ a new model for MPIs and a fragmentation function derived with the PROFESSOR [30] tool, as well as  $p_T$ -ordered parton showers. The main difference between the two tunes is the usage of the CTEQ5L PDFs [31] in Z1 and the CTEQ6L1 PDFs [23] in Z2. Using different PDF sets requires the adjustment of the parameter that defines the minimal momentum transfer in MPIs in order to keep the cross section of the additional scatterings constant. Tune 4C [32] of PYTHIA version 8 also uses a new MPI model, which is interleaved with parton showering, and the CTEQ6L1 PDFs.

During simulation and reconstruction, the simulated samples take into account an imperfect alignment as well as nonoperational channels of the tracking system.

## 5 Reconstruction

For the purpose of measuring the soft activity of the UE, the data are analysed down to very small transverse momenta of 0.3 GeV, exploiting the capabilities of the CMS tracking detectors. A potential neutral component of the UE, measurable only with the calorimeters, is neglected. Consequently, the jet clustering is performed on reconstructed tracks either from data or simulated events (track jets), and also on stable charged particles in generator events (charged-particle jets). Generator particles with mean lifetimes  $\tau$  such that  $c\tau > 10$  mm are considered to be stable.

### 5.1 Track selection

The performance and technical details of the CMS tracking with first collision data is described in [17]. The track selection of this analysis follows that of the conventional UE measurement as discussed in [4]. In detail, the following criteria are applied:

- high-purity track quality [17];
- transverse momentum  $p_T > 0.3$  GeV;
- pseudorapidity  $|\eta| < 2.3$ ;
- transverse impact parameter  $d_{xy} < 0.2$  cm;
- longitudinal impact parameter  $d_z < 1$  cm;
- relative track  $p_T$  uncertainty  $(\sigma_{p_T}/p_T) \cdot \max(1, \chi^2/N_{\text{dof}}) < 0.2$ , where  $N_{\text{dof}}$  denotes the number of degrees of freedom in the track fit.

These impact parameters are determined with respect to the primary vertex.

### 5.2 Charged generator particles

The influence of the detector on a particular observable is estimated by comparing the predictions, as given by a particle generator, before and after detector simulation, including trigger effects. To achieve a good correspondence to the track selection, the generated stable charged particles are required to satisfy  $p_T > 0.3$  GeV and  $|\eta| < 2.3$ . This minimum transverse momentum threshold and the restriction to charged particles significantly reduces the number of particles entering the clustering process.

### 5.3 Jet selection

No further selection on the transverse momenta of the jets is imposed. Because of the selection criteria on the input objects, however, they are implicitly restricted to be larger than 0.3 GeV. To avoid boundary effects in the jet-area determination, the absolute pseudorapidity of the jet axis is required to be smaller than 1.8, which is to be compared with  $|\eta| < 2.3$  for the input objects.

## 6 Detector unfolding

In order to compare data with theoretical predictions, the measurement must be corrected for detector response and resolution effects. In abstract terms, the connection between a true and the reconstructed distribution is expressed by a folding integral, which must be inverted to correct for the detector effects. Commonly, this procedure is referred to as unfolding or deconvolution. The technique adopted here to unfold the  $\rho'$  distribution is the iterative Bayesian approach [33] as implemented in the RooUnfold framework [34]. For this method the relevant distributions of a given observable are analysed before and after detector simulation and the detector response is expressed as a response matrix. To improve the statistical stability of the unfolding procedure, a wider binning and a reduced  $\rho'$  range are used compared to the uncorrected distributions.

It is found that the response matrices derived from different event generator tunes yield different results after the unfolding of the data distribution, which is a consequence of the difference in track multiplicities of the tunes. The tune Z2, which yields the best description of track-based observables, is used to unfold detector effects, while the others are employed only to derive the systematic uncertainties arising from this procedure.

## 7 Systematic uncertainties

The following sources of systematic uncertainties are considered: the trigger efficiency bias, the influence of the track selection, track misreconstruction and the reconstruction efficiency, the track jet  $p_T$  response, nonoperational tracker channels, and the tune dependence in the unfolding procedure.

Since most of the effects are found to be  $\rho'$ -dependent, suitable parametrisations are chosen to quantify them. From these parametrisations, the uncertainties are derived bin by bin by adding the different effects in quadrature. For variations in the requirements, for example from decreasing and increasing the track  $p_T$  requirement, symmetrised uncertainties are derived in the form of the average of the observed absolute deviations from the baseline scenario. Representative numbers for the uncertainties are summarised in table 1 apart from the trigger efficiency bias, which is found to be negligible, since the event selection criterion of at least four tracks required for a well reconstructed primary vertex is stricter than the trigger condition.

The only track selection criterion identified to have a significant impact on the observable is the minimal track  $p_T$ . Varying the threshold value of 300 MeV by  $\pm 10\%$  induces a systematic uncertainty on the  $\rho'$  distribution of about 2.0% at 7 TeV and 3.0% at 0.9 TeV. For the lowest  $\rho'$  bins, the effect increases dramatically to  $\pm 15\%$  at 7 TeV and  $\pm 16\%$  at 0.9 TeV.

The potential mismatch between the number of reconstructed tracks and the number of charged particles is estimated from simulated events to be 5%. A similar number is found for the reconstruction efficiency of nonisolated muons in data [35]. To quantify the influence of the tracking efficiency on  $\rho'$ , a random track from an independent sample is added to the analysed sample with a probability of 5% per existing track. Thus, the kinematic variables

Systematic effect	$\sqrt{s} = 0.9 \text{ TeV}$		$\sqrt{s} = 7 \text{ TeV}$	
	typ. size	max. size	typ. size	max. size
Track selection	$\pm 3.0$	$\pm 16 \text{ (low } \rho')$	$\pm 2.0$	$\pm 15 \text{ (low } \rho')$
Track reconstruction	$\pm 0.5$	$\pm 3.0 \text{ (low } \rho')$	$\pm 0.5$	$\pm 2.5 \text{ (low } \rho')$
Track-jet $p_T$ response	$\pm 4.0$	$\pm 5.0 \text{ (low } \rho')$	$\pm 2.0$	$\pm 4.0 \text{ (low } \rho')$
Nonoperational tracker channels	$\pm 2.5$	$-3.0 \text{ (low } \rho')$	$\pm 1.0$	$+1.5 \text{ (low } \rho')$
Unfolding & tune dependence	$\pm 9$	$\pm 10 \text{ (high } \rho')$	$\pm 4$	$\pm 16 \text{ (high } \rho')$

**Table 1.** Summary of systematic uncertainties on the  $\rho'$  distributions (in percent).

of the additional track follow the distributions predicted by the simulation. The effect of dropping each track with a probability of 5% is also studied. The total resulting influence on  $\rho'$  for adding false or losing real tracks is found to be around 0.5% in most bins.

The response of the track jet  $p_T$  measurement compared to charged-particle jets is another source of uncertainty. It is studied by shifting the  $p_T$  of each jet in the events by  $\pm 1.7\%$ . This number corresponds to the width of the transverse momentum response distribution when comparing jets from generated charged particles and their corresponding reconstructed track jets. As expected in the case of systematically increased transverse momenta, the  $\rho'$  spectrum is shifted towards higher values and vice versa. The magnitude of the effect is dependent on  $\rho'$  and ranges from about 4% for small  $\rho'$  to about 2.0% for large  $\rho'$  at  $\sqrt{s} = 7 \text{ TeV}$ . In the case of  $\sqrt{s} = 0.9 \text{ TeV}$ , the effect is more pronounced but it remains smaller than 5%.

Further sources of uncertainties are nonoperational tracker channels and imperfect alignment of the tracker components. These effects are studied by means of a special simulated data set, which assumes perfect alignment and all channels functional. Small values of  $\rho'$  are affected most, with a total systematic uncertainty of 1.0% at 7 TeV and 2.5% at 0.9 TeV on average.

The uncertainty arising from the response matrix in the unfolding procedure is evaluated by investigating the differences in the response in the different tunes. The measured distribution is unfolded with all four response matrices, and the average deviation of the D6T, Z1, and 4C results from those obtained with the Z2 tune are taken as the systematic uncertainty, which amounts to roughly 4% at 7 TeV and 9% at 0.9 TeV, increasing for higher  $\rho'$  values.

## 8 Results

As in conventional UE measurements it is possible for the  $\rho'$  observable to be investigated not only inclusively but also as a function of the hardness of an event, which is given by the “event scale”. In the conventional approach, this scale is usually defined by the transverse momentum of either the hardest track or hardest jet. In the present study, the natural choice for the event scale is the transverse momentum of the jet leading in  $p_T$  within the acceptance. In the next two subsections the inclusive and the event-scale-dependent results

on  $\rho'$  are presented without correction for detector effects. The unfolded results follow in subsection 8.3.

### 8.1 Inclusive measurement

Figure 1 shows the uncorrected inclusive  $\rho'$  distributions for data in comparison to the PYTHIA 6 tunes Z1, Z2, D6T, and the PYTHIA 8 tune 4C. The distributions are normalised to the observed number of events. All predictions deviate significantly from the measurements at both centre-of-mass energies, in particular for  $\rho'$  values larger than about 0.5 GeV. At  $\sqrt{s} = 0.9$  TeV PYTHIA 6 Z2 overshoots the data while PYTHIA 6 D6T and PYTHIA 8 4C are systematically too low. In comparison, PYTHIA 6 Z1 is closer to the measurement with some overestimation in the range of  $\rho'$  from 0.5 to 1.5 GeV at  $\sqrt{s} = 0.9$  TeV and a similar behaviour from 1.0 to 2.0 GeV at  $\sqrt{s} = 7$  TeV. For higher  $\rho'$ , Z1 undershoots the data. While PYTHIA 8 4C continues to exhibit too little UE activity at the higher centre-of-mass energy of 7 TeV, PYTHIA 6 D6T describes the data somewhat better. PYTHIA 6 Z2 changes from severely overestimating the UE to an underestimation at 7 TeV, hinting at a problem with the energy dependence of the UE in this tune.

### 8.2 Event scale dependence

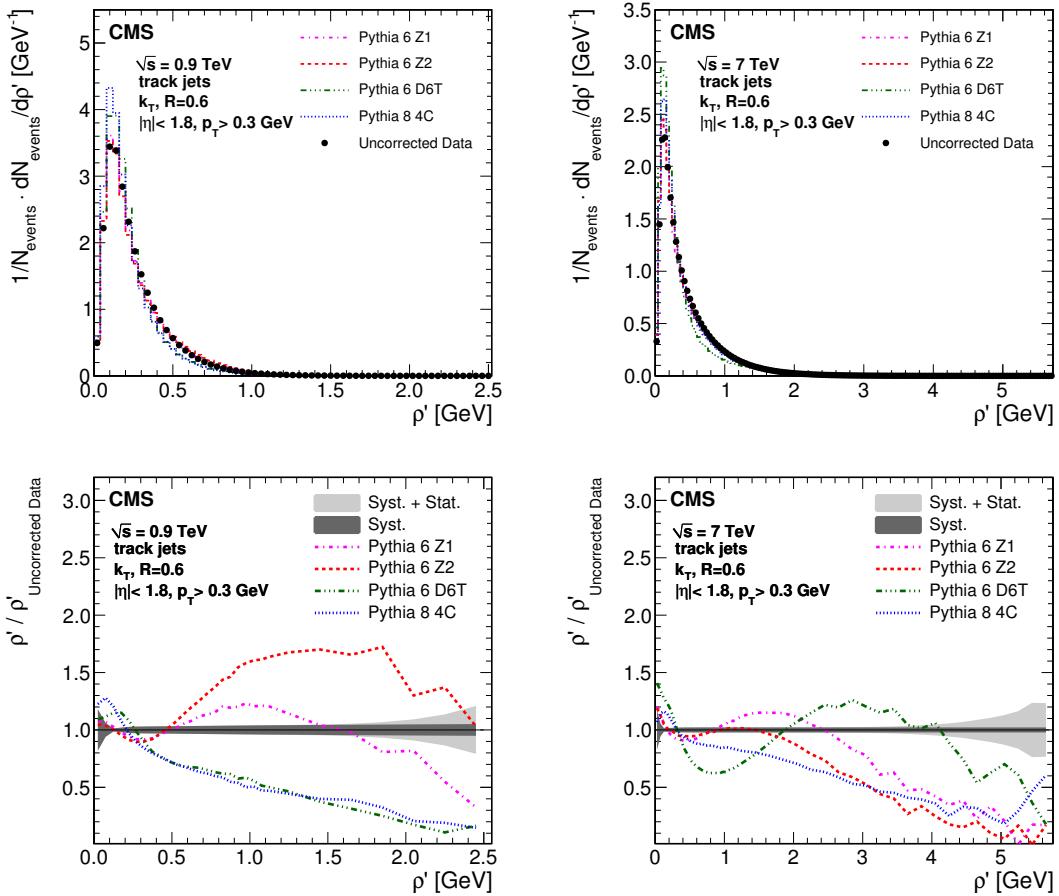

Figure 2 shows as examples the uncorrected  $\rho'$  distributions in the two slices of the leading jet  $p_T$  of  $3 < p_{T,\text{leading}} < 6$  GeV (left) and  $9 < p_{T,\text{leading}} < 12$  GeV (right) at  $\sqrt{s} = 7$  TeV. Of course, the additional binning in the hardness of the events effectively limits the accessible range in  $\rho'$  as well. The observed deviations of PYTHIA 6 Z2 or PYTHIA 8 4C from the measurements remain similar when going from an inclusive view to slices in event scale. In contrast to this, the comparison of PYTHIA 6 D6T and Z1 relative to the data does change. This can be seen even more clearly when concentrating on gross features of the distributions such as the peak values, means, or widths, which depend visibly on the event scale.

For completeness figure 3 presents the mean values  $\langle \rho' \rangle$  for all slices possible at 0.9 and 7 TeV centre-of-mass energy versus the leading jet  $p_T$  as event scale. In accordance with expectations from similar UE studies in the conventional approach, a steep rise at small event scales as well as a saturation or plateau region at high scales are exhibited. The increase of the UE activity with higher centre-of-mass energies is visible from the heights of the plateau regions, which roughly correspond to a ratio of 1.8, in agreement with observations of a ratio around 2 for conventional observables in [4].

With respect to the tune comparisons at 0.9 and 7 TeV, PYTHIA 8 4C always undershoots the average UE activity as characterised by  $\langle \rho' \rangle$ , PYTHIA 6 Z1 changes from agreement with data to an underestimation, Z2 from an overestimation to an underestimation, and D6T from a systematic underestimation to an overestimation for event scales larger than 10 GeV at 7 TeV centre-of-mass energy.

### 8.3 Unfolded results

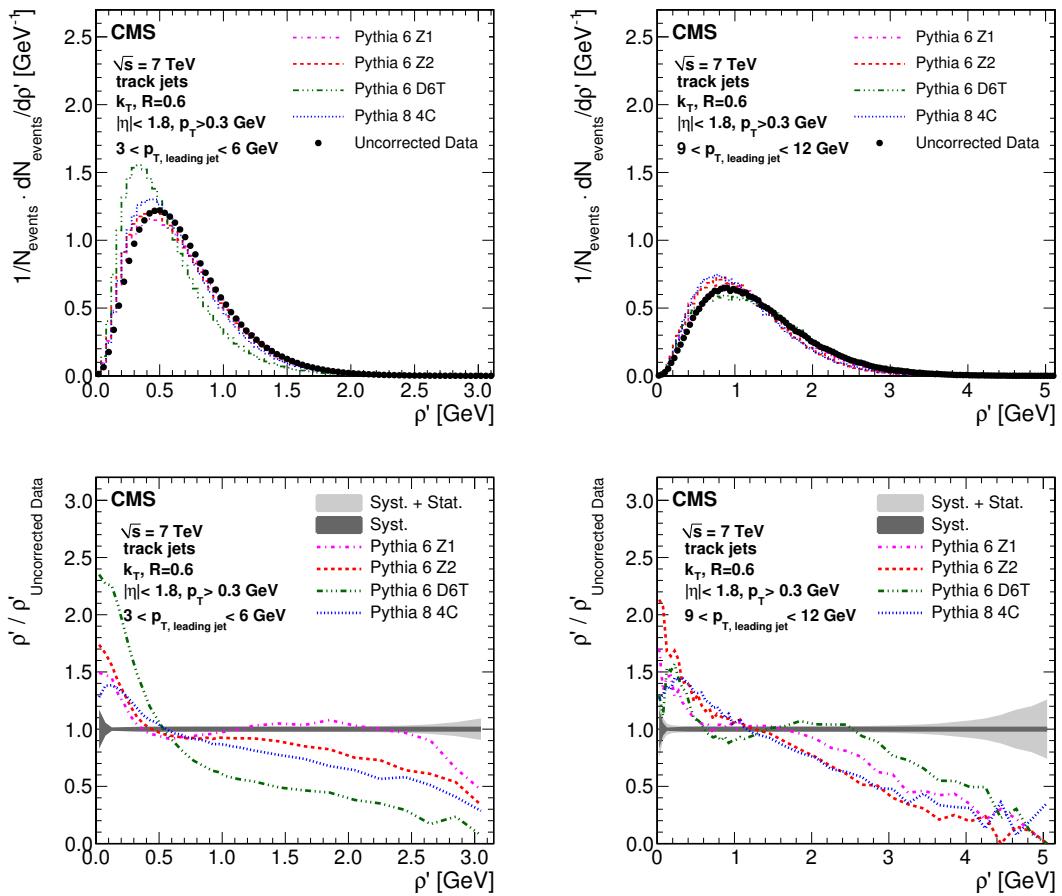

Figure 4 compares the inclusive  $\rho'$  distributions, unfolded with the Bayesian method, to the PYTHIA 6 tunes Z1, Z2, D6T, and the PYTHIA 8 tune 4C, but this time at the

**Figure 1.** Uncorrected inclusive  $\rho'$  distributions for data and simulation (upper row), and ratios of the PYTHIA 6 tunes Z1, Z2, D6T, and the PYTHIA 8 tune 4C relative to data (lower row) at  $\sqrt{s} = 0.9$  TeV (left) and  $\sqrt{s} = 7$  TeV (right). The dark grey shaded band corresponds to the systematic uncertainty and the light grey shaded band to the quadratic sum of the systematic and statistical uncertainty. The reach in  $\rho'$  is different at the two centre-of-mass energies.

level of stable charged particles. Because of the response differences among the tunes, a substantial systematic uncertainty is introduced by the unfolding, which is indicated in figure 4 by the difference between the dark and light grey shaded bands. Also the range in  $\rho'$  had to be limited to  $\rho' < 2.0$  GeV for  $\sqrt{s} = 0.9$  TeV and  $\rho' < 3.2$  GeV for  $\sqrt{s} = 7$  TeV to ensure the stability of the procedure. Nevertheless, the shape of the  $\rho'$  distributions is rather well preserved during the unfolding process and the same conclusions can be drawn as from the comparison of the uncorrected observable.

For the purpose of deriving the event scale dependence of  $\langle \rho' \rangle$ , the  $\rho'$  distribution in each slice of jet  $p_T$  must be unfolded independently using separate response matrices. The result is presented in figure 5 where the error bars are dominated by the uncertainty introduced through the unfolding procedure. Again, the observations are consistent with the uncorrected case as shown in figure 3 and the ratio of the plateau heights roughly corresponds to a factor of 1.8 between 0.9 and 7 TeV centre-of-mass energy.

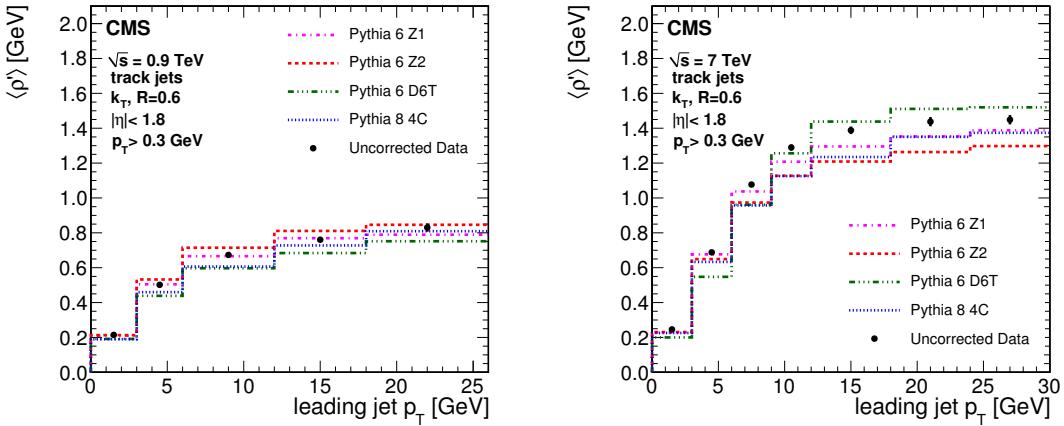

**Figure 2.** Uncorrected  $\rho'$  distributions in the two slices of leading track jet transverse momentum,  $3 < p_{T,\text{leading}} < 6 \text{ GeV}$  (left) and  $9 < p_{T,\text{leading}} < 12 \text{ GeV}$  (right) at  $\sqrt{s} = 7 \text{ TeV}$ . The reach in  $\rho'$  is different for the two slices in leading track jet  $p_T$ . The lower plots show the ratios of the different generator tunes to the reconstructed data. The dark grey shaded band corresponds to the systematic uncertainty and the light grey shaded band to the quadratic sum of the systematic and statistical uncertainty.

## 9 Summary

The jet-area/median approach to measuring the underlying event has been studied for the first time in a collider experiment at the two centre-of-mass energies of 0.9 and 7 TeV with the CMS detector. The measured distributions of the observable  $\rho'$ , based on this approach, are unfolded for detector effects and compared to predictions of several Monte Carlo event generator tunes before and after detector simulation. The substantial discrepancies observed among the various predictions and also between the predictions and the data demonstrate the sensitivity of the method and indicate the need for improved tunes at both centre-of-mass energies. None of the examined models describe the data satisfactorily.

Overall, PYTHIA 6 Z1 gives the best description of the data with some residual underestimation at  $\sqrt{s} = 7 \text{ TeV}$ . PYTHIA 6 Z2 varies from severely overshooting the data at 0.9 TeV to falling short of the data at 7 TeV, hinting at an inadequate setting of the  $\sqrt{s}$

**Figure 3.** Mean values of the uncorrected  $\rho'$  distributions versus leading track jet transverse momentum at  $\sqrt{s} = 0.9$  TeV (left) and  $\sqrt{s} = 7$  TeV (right) in comparison to the predictions by the different generator tunes. The error bars, which are mostly smaller than the symbol sizes, correspond to the quadratic sum of the systematic and statistical uncertainty.

dependence for the UE model. PYTHIA 8 4C almost always underestimates the UE activity, while PYTHIA 6 D6T does so only at 0.9 TeV or at small event scales but then rises too steeply with increasing hardness of the events. The general pattern of deviations from data by the considered PYTHIA tunes is similar to that observed with the conventional approach [4].

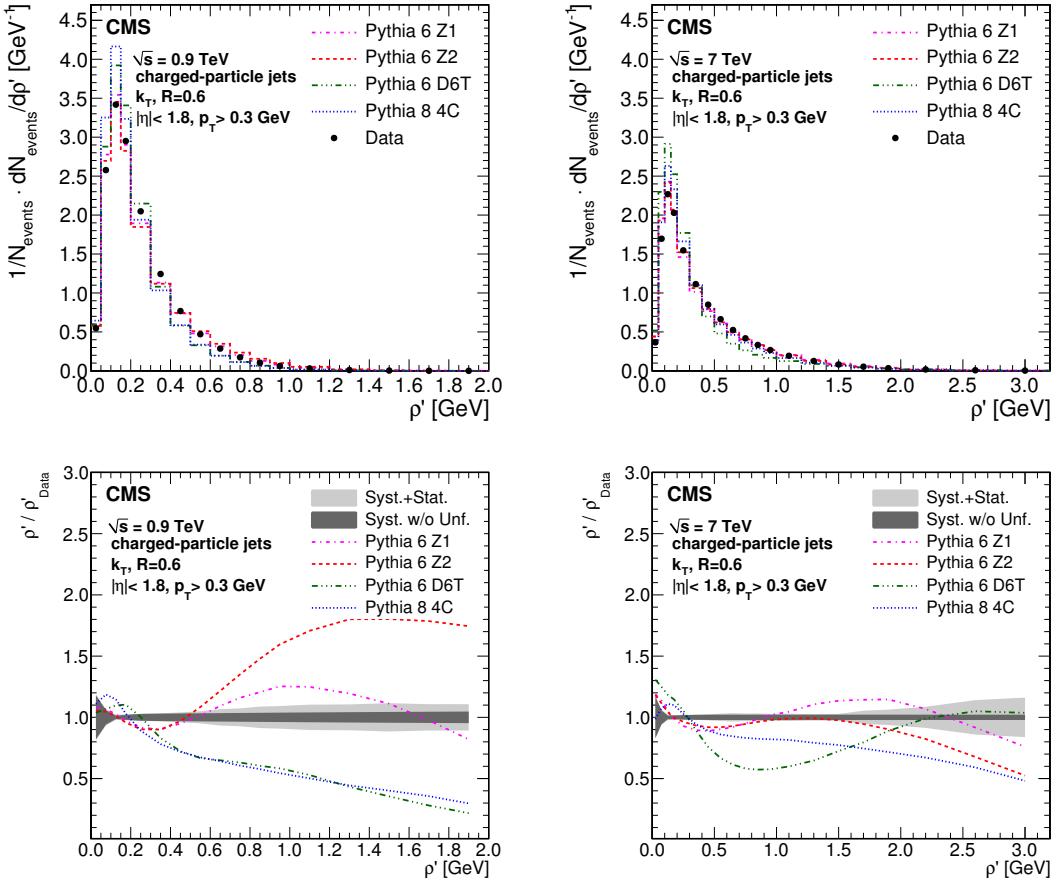

The mean  $\langle \rho' \rangle$  has also been investigated as a function of the transverse momentum of the leading jet. In agreement with the conventional analysis, a steep rise of the UE activity with increasing leading jet transverse momentum up to about 10 GeV is observed. For higher transverse momenta a plateau is reached. The ratio of the UE activity in this saturation region at 7 TeV to that at 0.9 TeV is approximately 1.8, which is close to the ratios of around 2 measured with the conventional observables.

In conclusion, the new observable  $\rho'$  based on the jet-area/median approach has been demonstrated to be sensitive to soft hadronic activity and offers an alternative view of the UE. The method is not restricted to minimum-bias events as examined here but can also be applied to different event topologies.

## Acknowledgments

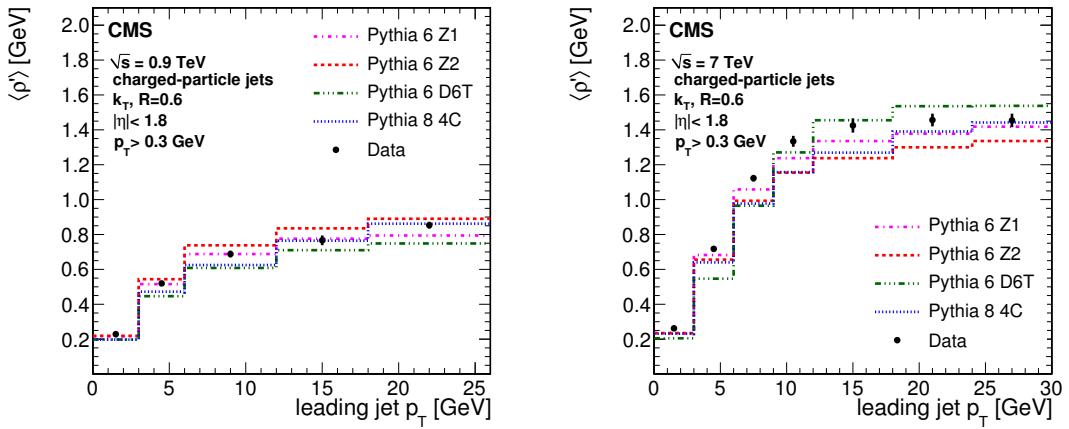

We thank G. Salam and S. Sapeta for help in defining the modified observable  $\rho'$ .

We congratulate our colleagues in the CERN accelerator departments for the excellent performance of the LHC machine. We thank the technical and administrative staff at CERN and other CMS institutes. †: Deceased

- 1: Also at CERN, European Organization for Nuclear Research, Geneva, Switzerland
- 2: Also at National Institute of Chemical Physics and Biophysics, Tallinn, Estonia
- 3: Also at Universidade Federal do ABC, Santo Andre, Brazil
- 4: Also at California Institute of Technology, Pasadena, U.S.A.
- 5: Also at Laboratoire Leprince-Ringuet, Ecole Polytechnique, IN2P3-CNRS, Palaiseau, France
- 6: Also at Suez Canal University, Suez, Egypt
- 7: Also at Cairo University, Cairo, Egypt
- 8: Also at British University, Cairo, Egypt
- 9: Also at Fayoum University, El-Fayoum, Egypt
- 10: Now at Ain Shams University, Cairo, Egypt
- 11: Also at Soltan Institute for Nuclear Studies, Warsaw, Poland
- 12: Also at Université de Haute-Alsace, Mulhouse, France
- 13: Now at Joint Institute for Nuclear Research, Dubna, Russia
- 14: Also at Moscow State University, Moscow, Russia
- 15: Also at Brandenburg University of Technology, Cottbus, Germany
- 16: Also at Institute of Nuclear Research ATOMKI, Debrecen, Hungary
- 17: Also at Eötvös Loránd University, Budapest, Hungary
- 18: Also at Tata Institute of Fundamental Research - HECR, Mumbai, India
- 19: Now at King Abdulaziz University, Jeddah, Saudi Arabia
- 20: Also at University of Visva-Bharati, Santiniketan, India
- 21: Also at Sharif University of Technology, Tehran, Iran
- 22: Also at Isfahan University of Technology, Isfahan, Iran
- 23: Also at Shiraz University, Shiraz, Iran
- 24: Also at Plasma Physics Research Center, Science and Research Branch, Islamic Azad University, Teheran, Iran
- 25: Also at Facoltà Ingegneria Università di Roma, Roma, Italy
- 26: Also at Università della Basilicata, Potenza, Italy
- 27: Also at Università degli Studi Guglielmo Marconi, Roma, Italy

- 28: Also at Laboratori Nazionali di Legnaro dell' INFN, Legnaro, Italy
- 29: Also at Università degli studi di Siena, Siena, Italy
- 30: Also at University of Bucharest, Faculty of Physics, Bucuresti-Magurele, Romania
- 31: Also at Faculty of Physics of University of Belgrade, Belgrade, Serbia
- 32: Also at University of Florida, Gainesville, U.S.A.
- 33: Also at University of California, Los Angeles, Los Angeles, U.S.A.
- 34: Also at Scuola Normale e Sezione dell' INFN, Pisa, Italy
- 35: Also at INFN Sezione di Roma; Università di Roma "La Sapienza", Roma, Italy
- 36: Also at University of Athens, Athens, Greece
- 37: Also at Rutherford Appleton Laboratory, Didcot, U.K.
- 38: Also at The University of Kansas, Lawrence, U.S.A.
- 39: Also at Paul Scherrer Institut, Villigen, Switzerland
- 40: Also at Institute for Theoretical and Experimental Physics, Moscow, Russia
- 41: Also at Gaziosmanpasa University, Tokat, Turkey
- 42: Also at Adiyaman University, Adiyaman, Turkey
- 43: Also at The University of Iowa, Iowa City, U.S.A.
- 44: Also at Mersin University, Mersin, Turkey
- 45: Also at Kafkas University, Kars, Turkey
- 46: Also at Suleyman Demirel University, Isparta, Turkey
- 47: Also at Ege University, Izmir, Turkey
- 48: Also at School of Physics and Astronomy, University of Southampton, Southampton, U.K.
- 49: Also at INFN Sezione di Perugia; Università di Perugia, Perugia, Italy
- 50: Also at University of Sydney, Sydney, Australia
- 51: Also at Utah Valley University, Orem, U.S.A.
- 52: Also at Institute for Nuclear Research, Moscow, Russia
- 53: Also at University of Belgrade, Faculty of Physics and Vinca Institute of Nuclear Sciences, Belgrade, Serbia
- 54: Also at Argonne National Laboratory, Argonne, U.S.A.
- 55: Also at Erzincan University, Erzincan, Turkey
- 56: Also at Kyungpook National University, Daegu, Korea
